Causation of Contused and Lacerated Wounds.—Contused and lacerated wounds differ only in degree. In contusions the intestinal walls are bruised, in lacerations they are torn. These forms are commonly due to external violence, and when thus caused both varieties may be well marked at or near the same situation. A considerable degree of external violence is required to cause a laceration or a severe contusion of the intestines, owing to their mobility and flexibility, and also to the nature of their investing tissues. Despite this fact, however, cases of laceration occur from blows so slight, or through agents of such a character, that no injury is done to the abdominal walls. MacCormac has reported several such cases. Usually the agents transmitting the force have a blunt outline. The passage of the wheel of a loaded vehicle over the abdomen offers a frequent illustration of the manner in which the violence is inflicted; also a blow from the clenched hand or from the kick of a horse or a man, especially if the intestine be forced against the spinal column, or if the violence be received at a point where dense fecal impaction exists. Partial distention, according to Curtis, who made an analysis of 116 cases, diminishes the danger of rupture, while great distention of an isolated loop increases it, even for a loop not in contact with bony parts. The intestines may be bruised and even lacerated by imprudent manipulations for the reduction of herniæ, and the colon has been torn by the incautious introduction of the hand or an instrument into the sigmoid flexure. Contusions with or without lacerations have been caused by kneading the abdomen to overcome intestinal obstructions dependent on fecal impaction, and rupture has occurred from the force exerted by circumscribed collections of gas generated in morbid obstructive conditions. The force of spent pieces of shell has caused laceration of the small intestine. In 113 of the cases analyzed by Curtis, the duodenum was injured in 6 instances, the jejunum in 44, the ileum in 38, other portions of the intestine in 21, and the colon in 4.

Non-penetrating gunshot wounds of the intestine are essentially contused injuries of that structure. However, in penetrating gunshot injuries, the character of the intestinal wound assumes a different aspect, due, of course, to the penetration of the intestine by the missile causing the abdominal injury. Still, in these instances one frequently meets with both contused and lacerated wounds, independent of those due to direct penetration, since the mobility of the intestine or a mere impingement upon it of the missile fails to cause direct penetration. It is proper to say, however, that the borders of a penetrating gunshot wound of the intestine possess the characteristic features often of lacerated and contused wounds, although, for obvious reasons, in a much less degree.

Penetrating gunshot wounds of the intestine are more frequent in civil than in military life, as in the latter the trunk is exposed as little as possible and the missiles fly high, while in the former the attacks are often unexpected, and, therefore, the recipient is illy prepared to guard against them. Moreover, the range of the former is shorter, therefore the aim is better. It is interesting to note at this time that the percentage of gunshot injuries of the abdomen that are reported as resulting from the late war, is astonishingly small (about 0.035), while those of the head were 0.15. The increased percentage of the latter is due to the greater exposure of this part of the body. No definite estimate can be made prior to investigation of the number, size, direction, or exact nature of the injuries of the intestine that may follow penetrating gunshot wounds of the abdomen. The original text (see Vol. IV.) discusses this in greater detail.

Abdominal Symptoms.—Pain, tenderness, tympanites, and bloody stools, with or without the protrusion of the viscus and the escape of the intestinal contents, are common symptoms of intestinal wounds. They are greatly modified, however, with reference to their presence and their association with each other, by the nature of the wound itself.

Pain and Tenderness.—Pain is not a reliable symptom. Soon after the occurrence of an injury, there may be little, or indeed none, even when perforations are present. Commonly, however, pain and tenderness are among the first of the abdominal symptoms. Located primarily at the seat of the wound, it is dull or lancinating in quality, the former being more characteristic of contused wounds. As a rule it increases rapidly, becomes burning in character, and is accompanied by exquisite tenderness of the abdomen, retraction of the thighs, and obstinate constipation. It is increased by any muscular exertion, even the act of breathing. Sometimes there are griping pains with a desire to stool. Retention of urine may occur, due to the shock, to the peritonitis, or to the treatment employed.

Emphysema.—This sign is not associated very frequently with penetrating wounds of the abdomen, but when present is usually due to the escape of intestinal gases into the connective tissue situated between the intestine and the abdominal walls; hence it is associated especially with injuries of those portions of the intestinal tract that are not entirely surrounded by peritoneum. It may be limited to the immediate neighborhood of the injury, or may become general by spreading gradually into

the surrounding tissue, and it also may be due entirely or in part to a complicating wound of pulmonary tissue. Emphysema has been considered by some writers as a certain sign of intestinal perforation, when associated with a suspected penetrating abdominal wound. Its diagnostic value is much lessened, however, by the fact that it has been frequently observed in connection with non-penetrating wounds of the abdominal wall, one such instance, at least, having fallen within the observation of the writer. If decomposing processes occur in the course of a penetrating wound of the abdomen, emphysema may result even though the intestines themselves have not been injured. In such cases, however, the appearance of the emphysema is delayed.

Contused Wounds.—The diagnosis of contused and lacerated wounds can readily be made from that of all other forms, but to differentiate between these two is more difficult. There will be a history of abdominal injury received in some such way as already indicated. There may be external evidences of such injury, though in some instances there are none. If the intestinal wound be a *contused* one, there will be evidence of *shock*. *Respiration* may be modified by the pain attendant on the act of breathing. *Vomiting* is a frequent but not constant symptom. *Pain* is usually present in the beginning, not so acute as in lacerated wounds, but dull, deep-seated, and burning, denoting a beginning inflammation. These symptoms may subside in a few days, or they may be quickly followed by a sudden increase in the pain and more urgent manifestations of peritonitis, or by collapse. These unfavorable symptoms may be caused by the rapid increase of a localized inflammation, by a sudden hemorrhage from a previously contused vessel, or more commonly by a sudden extravasation following sloughing of some portion of the intestinal wall. The constitutional symptoms keep pace with the local. The temperature rises, the pulse becomes more frequent and harder, and the patient soon shows evidence of collapse.

The degree of tympanitic distention of the abdomen is usually proportionate to the extent and intensity of the inflammation. The tympanites may be due to air in the peritoneal cavity or in the intestine. In the former condition it comes from a wound in the gut, and in contused wounds it will, therefore, occur at or soon after the exacerbation of symptoms, while in lacerated it follows quickly the intestinal injury. Tympanites due to intestinal distention comes more slowly and is less in degree. *In lacerated wounds*, fecal extravasation occurs as a rule. It was present in 107 out of 113 cases (Curtis). The symptoms will, therefore, appear earlier than in contused wounds and be more severe. In both varieties there may be vomiting of blood, particularly if the duodenum or jejunum be injured. Blood may also be passed at stool, and if the amount be small and clotted, it indicates injury to the ileum. If the blood has to traverse a considerable portion of the intestine, it will be darkened in color and consistency by the intestinal fluids. The possibility of coincident diseases of the intestines causing hemorrhage must not be forgotten.

Nor must it be forgotten that a patient may have received either a contused or a lacerated wound of the intestines, and yet present no symptoms for a few hours. MacCormac has reported one such case, and two others where vomiting was the only symptom, yet all three had rupture of the intestine and died within forty-eight hours.

Hydrogen gas has been recommended by Senn as a means of determining whether or not, in a case of penetrating abdominal wound, there co-exist perforations of the intestines. He has demonstrated that under slight but steady pressure, the patient being relaxed by an anæsthetic, the gas may be forced from the anus past the ileo-cæcal valve to the mouth. If perforations exist the gas escapes into the peritoneal cavity, its presence being denoted by free tympanites, loss of liver-dulness, etc., or it will appear at the abdominal wound, where it may be ignited. If the distention follows the line of the colon, and, after passing the valve, be confined to the umbilical and hypogastric regions, it indicates that the intestine is intact. The gas in passing the valve causes a blowing or gurgling sound which may easily be heard with a stethoscope. The method of using it is as follows: The gas, generated in the ordinary manner (care being taken to have it pure), is collected in a rubber bag holding about four gallons. This bag is connected with a rectal tip by means of a rubber tubing and stop-cock. The rubber bag being filled, the rectal tip is inserted and the margin of the anus pressed against it to prevent the return of the gas; the bag is now subjected to gentle pressure, the valve yielding to a force varying from one-half to two pounds. If the external wound points to the possibility of stomach injury, then insufflation should be practised through a stomach tube. The disadvantages of the method are that it prolongs the operation, sometimes makes the returning of the bowels a very difficult matter, and occasionally, when perforations exist, it fails to discover them—items which, according to the majority of observers, outweigh its advantages. In addition to this, there exists the danger of forcing a portion of the intestinal contents into the abdominal cavity, particularly if they be fluid, and be located in or at the point of perforation.

Local Treatment of Hemorrhage.—Hemorrhage through the abdominal wound may arise either from the wound itself or have an intra-abdominal origin. In either case the indication is to tie the bleeding vessel. This can be easily done if it be situated in the abdominal wall, although it may be necessary to enlarge the opening for that purpose. Bleeding from within the cavity is considered in the great majority of cases a positive indication for laparotomy. Its treatment by and during laparotomy will be considered under gunshot wounds. If, in a given case, for any reason laparotomy may not be performed, the treatment must be palliative. The patient is kept quiet, and cold applications made to the abdomen. The external wound must remain unobstructed, so as to permit the free escape of blood that might otherwise collect in the abdominal cavity. A dressing of moist antiseptic gauze will serve the double purpose of protecting the wound and acting as a drain. In these admittedly hopeless cases, it is not impossible that pressure on the abdominal aorta, combined with transfusion, may prolong the patient's life. Should the hemorrhage thus be controlled, laparotomy during continuance of the pressure may yet offer an additional means of preserving life.

Treatment of Lacerated and Contused Wounds.—A lacerated or contused wound of an intestine may or may not admit of abdominal section. There is, of course, less danger of fecal extravasation in such a wound than in one associated with abdominal penetration, as the penetrating agent may carry the infection from all parts of the wound into the peritoneal cavity. If the symptoms are mild and rupture seems improbable, adopt the expectant plan. At all events, the performance of laparotomy should be deemed unwise in these cases after sufficient time has elapsed to permit the formation of adhesions contiguous to the injured portion. Severe hemorrhage, or serious visceral lesion, demands prompt operative interference. Laparotomy to be serviceable must be done early, and not left until peritonitis sets in. In a collection of eleven cases operated on after a few hours had elapsed, and as peritonitis was beginning, all died. Shock, usually great in these cases, is much increased by a long operation. For this reason many advocate the formation of an artificial anus. The choice between this and enterorrhaphy will depend in a measure on the experience and preparation of the operator. A wound located at a point of the intestine that would lead to rapid impoverishment of the patient from the formation of an artificial anus, should be treated by enterorrhaphy, even though the patient be exposed to greater immediate danger.

Treatment of Punctured and Incised Wounds.—In all uncomplicated punctured wounds of the intestine not more than 8 mm. in length, the question of abdominal section need not be raised. If it be thought larger than this, the measures adopted will be governed directly by the size of the wound and acuteness of the symptoms.

Incised wounds of the intestines are more dangerous than punctured ones, because of the greater liability to hemorrhage and extravasation. Their general treatment is similar to that of other varieties. In performing laparotomy the incision is usually made in the line of the wound rather than in the median line, because it affords the most direct route to what is usually a limited injury.

TREATMENT OF GUN-SHOT WOUNDS.—In opening the peritoneal cavity, the initiatory incision should be made in the median line, especially when it shall appear that if the opening be made at the seat of injury, it will not offer an adequate opportunity for a proper inspection and treatment of the injured parts. The probable direction taken by the missile should be considered in all such instances. It has been advised, and wisely, that when the intra-abdominal wound is probably limited to the more fixed portions of the intestinal tract, or to other abdominal viscera, in the absence of symptoms of hemorrhage the incision be made in the line of the abdominal wound. After opening the peritoneal cavity, instead of using forceps, which bruise the tissues, to limit peritoneal retraction, a long suture of silk or catgut should be passed through the peritoneal borders for this purpose, and held by an assistant or otherwise properly anchored.

The agents employed in repairs of the intestine include materials for ligatures, sutures, etc.; carbolized iron-dyed silk may be employed for both purposes. Antiseptic catgut of small sizes may be used exclusively for ligatures, although some prefer to rely solely on silk. The needles required for sewing peritoneal and intestinal surfaces will depend on the preference of the operator, some using curved needles of small size and without sharp edges, others ordinary straight, slender sewing needles. The latter are particularly serviceable in introducing the Lembert suture. In addition, there are required thumb and mouse-tooth forceps to raise the borders of the wound, artery and needle forceps for obvious purposes, large catch-forceps with horseshoe-shaped blades to close the openings at the side of the intestine, of a similar shape, two or three long-bladed catch-forceps with the blades protected by rubber tubing to compress the intestine transversely, holding back its contents above and below the wound. (Several instruments have been devised for this, but the fingers of an assistant are best and safest.) Curved and straight scissors, aneurism needle, grooved director, scalpels, and other common surgical instruments are also necessary.

After opening the abdominal cavity, the blood and fecal matter under observation should be removed with small sponges as soon as seen. This should be done very carefully, when possible by gentle pressure rather than by wiping movements, as the latter provoke the further spread of the infecting agents. In either instance, a sponge should be changed with each effort at removal. The bleeding points immediately under notice should be tied. It is important to remember that penetrating intestinal wounds should be closed as soon as found, otherwise they may escape notice, and thereby furnish an additional risk of still further infecting the peritoneal cavity.

The repair of the intestine should be accomplished by one of two methods: 1, by directly closing the openings; 2, by excision of a portion of the intestine and the union of the divided extremities, which union may be accomplished by either circular enterorrhaphy or lateral anastomosis. The former method may be done when the closure of the wound will not diminish the intestinal calibre more than one-third. Either of the latter methods when the gut is extensively injured. In certain wounds where direct closure will narrow the calibre more than one-third, additional room may be gained by closing the wound transversely. To do this it may be necessary to increase the length of the wound by making longitudinal incisions at either end of it of suitable and equal lengths. The intestinal wall is then grasped at corresponding points on opposite sides, and drawn upon; the longitudinal wound is thus converted into a transverse one, and in this position its borders are united. By this means a certain amount of "elbowing" is produced. While, as a rule, it is unwise to trim the borders of intestinal wounds, yet care should be taken to examine the border of a wound contiguous to an important vessel, to ascertain if the integrity of the vessel be endangered; otherwise the closure without this precaution may be followed by secondary hemorrhage.

The wound may then be closed by either the Gely, Lembert, or continuous sutures. A double row of the Lembert or continuous varieties may be made, or a single row of each instead, or the Czerny-Lembert. (Of the continuous varieties, Treves recommends the right-angle continuous suture of Cushing.) See article on Sutures.

The sutures, to be reliable, must go down to and embrace a thread or two of the submucosa, and not be more than three lines apart. The best material for suturing the intestine is the loose-textured carbolized iron-dyed silk.

If the mesenteric border only of the intestine be injured, the injured portion of the gut should be excised, because gangrene is liable to follow from injury to the vessels of this part.

When the intestine is completely severed, either by the original injury or the knife of the surgeon, the difficulty of adjusting the cut borders is much increased. The portion to be repaired must be drawn well out of the abdominal wound and carefully isolated by sponges and towels that completely prevent blood, fæces, etc., from entering the abdominal cavity. The uppermost extremity of the divided intestine will be known by the greater amount of fecal matter seen at its open end. The intestinal contents must be pushed aside for some distance from the part to be operated on, and the bowel occluded above and below. This may be done by using the clamps already referred to, or by making a hole in the mesentery and ligating the intestine either with a cord of iodoform gauze or a flat india-rubber band. The fingers of an assistant serve better than anything else. The use of the clamps may, as shown by Parkes, cause sloughing if carelessly or continuously applied. The excision is made with sharp, straight-bladed scissors, at a right angle with the long axis of the intestine. The length of the portion removed will depend on the extent of the injury; it should always be sufficient to include it, even though it be six or eight inches in extent, and where multiform perforations exist near each other, it is advised to include them in one resection, even if the intestine removed be three feet long. The danger, however, of removing a so large and absorbing surface, must be remembered.

The vascular supply of the intestine at the seat of injury must be carefully examined, and all that portion of gut excised that has an impaired supply of blood, else gangrene of the bowel may ensue. In fact, it is a wise precaution in excision always to divide the gut at those points which will afford the best vascular supply to the extremities to be united—that is, close to the entrance of a mesenteric vessel into the unimpaired portions. The mesentery corresponding to the portion of gut removed can be cut away in the form of an isosceles triangle, the base of which shall correspond to its intestinal attachment, or it may be ligated *en masse*, or in sections at its point of attachment, and allowed to remain free in the abdominal cavity. Parkes and others consider the latter plan unsafe, since, owing to the feeble vitality of its tissue, gangrene of the distal extremities of the mesenteric stumps frequently ensues. Parkes advises that the entire mass be included in one ligature drawn tight enough to check the bleeding, and that after the intestine has been united, the stump be stitched to the seat of operation, thereby forming again as nearly as possible a continuous mesentery. This method was in his experiments followed by less mortification. Another method is to make two incisions, one on each side of the mesenteric vessels, at a distance of about half an inch from them, through the wall of the intestine in its long axis corresponding in length to the portion of the intestine to be removed. Tear away the mucous lining of this mesenteric strip, and unite its peritoneal borders by a continuous suture of fine catgut. After the excision is completed

and the ends of the intestine have been united, the mesenteric strip will present a looped appearance due to the approximation of the intestinal extremities. The opening of this loop should be united by sutures, and the opposed surfaces of mesentery should also be transfixed, to prevent the formation of a pocket there. When the ligature *en masse* is employed, it is not considered safe to use catgut.

As soon as all hemorrhage is checked, the extremities of the intestines are approximated by an assistant and some form of suture is introduced. The suturing is begun at the mesenteric border, care being taken to thoroughly close the triangular space at this point caused by the reflection of the peritoneum from the walls of the intestine. After this, the protruding mucous membrane is pushed into the intestine and a suture is introduced at each of the three remaining aspects of the bowel, and then the intervening spaces are properly sewed. This is a better plan than to begin to sew at any given point and go directly around. In no instance should a suture be passed through the mucous membrane. If a Lembert or Gely be used, at least three to four lines of peritoneum should be included in the grasp of the suture at each extremity of the intestine. A suture should be drawn only sufficiently tight to bring the severed borders in close apposition, for if drawn too tightly the tissue grasped by it will slough. If a single row of sutures alone is to be made, they should be placed about five millimetres apart. If a double row is to be employed, those of the first can be deposited within six or seven millimetres of each other, and those of the second at intervals between the former. After the bowel is united, it is well to return to the mesenteric border. This is the weakest portion of the wound. It should be covered by stitching the two peritoneal layers of the mesentery over it, or by an omental graft.

A great many instruments and agents have been devised and recommended for the purpose of holding the divided ends of the bowel open while it is being sutured, but they are all or nearly all useless.

Omental Grafting.—In certain experiments on dogs, Dr. Senn fixed a flap of omentum over the seam of an enterorrhaphy, the free or distal end being attached over the seam, the proximal remaining continuous with the omentum. These soon grew in place and thus reinforced the bowel. To avoid the danger of strangulation occurring through the loop thus formed, isolated grafts were employed and fixed round the suture. In every instance they retained their vitality. The intestinal peritoneum is lightly scarified before the flap is put in position, and in a few hours it is adherent.

Senn's operation for intestinal anastomosis by means of bone plates, though devised to meet the requirements in cases of obstructive disease of the intestine, is yet applicable to certain cases of injury, especially when time is a very important element.

Recently intestinal anastomosis is being performed without the use of bone or any other form of approximation-plates. The advocates of this method claim for it exemption from the special dangers following the use of approximation-plates, viz., leakage, irritation and suppuration or hemorrhage, also obstruction from the plates themselves, or, later, from contraction of the cicatrix, etc. The operation, as described by Abbe, is briefly as follows: The resected ends of the intestine are inverted and closed by Lembert sutures approximating the serous surfaces. They are then overlapped to the extent of five inches and held there by two rows of continuous Lembert sutures, each row being an inch longer than the proposed opening. These rows are straight, in the long axis of the gut, parallel, one quarter of an inch apart, and are both to be on one side of the anastomotic opening. The needle with its thread is to be left at the end of each row ready to be continued. The openings in the bowel are now made about four inches long, parallel with and one-quarter of an inch distant from the nearest row of serous sutures. The bleeding points are clamped and the clamps left on. A suture is then started at one end of the wound and unites by a continuous overhand stitch, which penetrates the entire thickness of the intestinal wall, the cut edges lying near to the rows of serous sutures. The free or more remote edges are whipped in turn by separate threads. This controls the bleeding without ligatures, the clamps being removed as they are reached, and it also prevents any union of the edges at the angles of the wound. The serous surfaces around the openings are now united by a continuation of the first two rows of sutures, their relations to each other and to the opening being preserved and ending where they began.

Cleansing the Peritoneal Cavity and Closing the Abdominal Wound.—All the bleeding points must be closed by ligaturing if possible, if not, then by cautery. It must not be forgotten that the tendency of intra-abdominal vessels to bleed when not exposed to the air is very great; therefore a simple oozing before the closure of the abdominal walls is likely to become a formidable hemorrhage thereafter; and even though the secondary oozing be not sufficient to imperil the life by loss of blood, it is liable to do so by causing inflammatory or septic processes. The blood, other fluids, fecal matters, and all other foreign agents must be removed from the abdominal cavity and its contents and culs-de-sac thoroughly wiped by warm soft aseptic sponges soaked in Thiersch's fluid, a two per cent. solution of carbolic acid, or a solution of bichloride of mercury (1 to 10,000). Too great care cannot be taken in sponging away the foreign matter. As already stated, the same portion of the sponge should be applied to a serous surface but once, for to apply it repeatedly causes quite as surely the dissemination as the removal of the irritating agents.

Malcolm, of London, advises flushing out the abdominal cavity for the purpose of adjusting naturally the intestinal folds. Water or antiseptic solution at the temperature of the body is poured into the cavity from a pitcher. The intestinal folds floated up, subside later into their normal positions. The fluid is poured in until it returns clear. That remaining in the cavity is siphoned off or sponged out thoroughly. This flushing with hot fluid also aids in cleansing the peritoneal cavity, and, besides, acts as a stimulant.

The abdominal wound should be closed by two rows of sutures, a superficial and a deep. The latter should be a continuous one of strong silk, and should include the serous and subserous tissues and the transversalis fascia. The practice of making a deep row of interrupted sutures widely separated, or of including the whole thickness of the abdominal wall in one such row, is to be condemned. The pockets or dimples of peritoneum which are thereby formed between the stitches invite the occurrence of hernia. The superficial row may be of silk or catgut, interrupted or continuous. If necessary, the wound may be drained. And last of all, an antiseptic dressing is to be applied. The patient should be quieted by small doses of an opiate; the diet should be light at first and of a nature to leave little or no residue. The bladder should be evacuated with a catheter.

PROGNOSIS.—Ruptured or lacerated wounds have thus far proved more fatal than any of the other forms. Of five cases reported during the late war all were fatal. Curtis reports eight cases which were operated on, and all died. Since then several others, in which laparotomy was performed, have been reported, only one of which, that of Crofts, was successful.

The prognosis in gunshot wounds of the intestines, when treated by laparotomy, has of late years vastly improved. In 1887, Morton published a series of twenty-two cases with a little less than twenty-three per cent. of recoveries. About the same time MacCormac collected thirty cases in which laparotomy had been performed (Morton's were included), and gave the recoveries at a little over twenty-three per cent. Since then a collection of thirty-five cases shows eighteen recoveries, or a little over fifty-one per cent.

Of stab wounds which were operated on, Morton reported nineteen cases with sixty-three per cent. recoveries; MacCormac eighteen cases with over fifty-five per cent. of recoveries. A collection of nineteen cases made since then gives over seventy-nine per cent. of recoveries.

Joseph D. Bryant.

INTRA-UTERINE TAMPON.—The present methods of treating morbid conditions of the interior of the uterus are revolutionary when compared with the methods of a generation ago. Nay, they are revolutionary when compared with the methods of some teachers who are still high in authority, and deservedly so. That which in all past ages of medical science and practice has been considered *noli me tangere* is now approached with perfect unconcern, if with perfect cleanliness, and with clear foresight and expectation of beneficent results. The cases are rare indeed in which this expectation is disappointed if the manipulation has been attended by the requisite cleanliness and without undue rudeness.

It must ever be remembered, now as well as in preantiseptic days, that the uterus is a contractile organ, that it is enormously vascular, and that it is enormously absorptive, and no one should invade the organ without due regard for this headlight. Another point of great importance which has received due recognition only in very recent times, is that morbid secretions or accumulations within the uterus should be drained away as thoroughly as they would be drained from any other cavity; that is, the principle of drainage applies to the uterus as well as to other cavities containiug poisonous material, and if such drainage is not free and unobstructed the chances of mishap are very great. Many of the ills of womankind are due to the fact that uterine drainage has been ignored or misunderstood. If nature provided an outlet for decomposing material, well and good, but if not, nature and not man must be held accountable, to the great detriment, however, of the patient. Such reasoning has filled many grave-yards, and is in harmony with that other sophistry, "meddlesome midwifery is bad"—apologies, both, for the timid and the ignorant. The intelligent management of uterine drainage is one of the most valuable adaptations of modern uterine pathology, and it is the tampon more than any other means or instrument which has made such treatment efficacious.

That the unimpregnated uterus is susceptible of dilatation is a fact which has long been known, but only in recent years has dilatation been practised to any great extent. The use of tents composed of various materials has been advocated and practised for many years, but owing to imperfections in the materials used and want of care in the way of using them disaster has not infrequently resulted, and the profession has come to look upon them with more or less distrust. The field of their utility was believed to be limited, and they were often used with fear and trembling, perhaps, when no other means seemed available. The inflatable rubber bag invented by Barnes for the facilitation of the first stage of labor was a most ingenious and valuable device, but the material was unreliable and might betray one in the hour of utmost need. The stems of glass, rubber, and metal which have been devised by Sims, Peaslee, Wylie, and others, have served, and still serve, a useful purpose in demonstrating the dilatability of the unimpregnated uterus, and the many useful ends which can be subserved with an open uterine canal and free drainage. The powerful uterine dilators which are now in such common use, and which are, for the most part, modelled after the powerful instrument of Sims, must be mentioned in connection with the means which have been, and still are, used for the dilatation of the uterus, and for preparing it for the use of the curette or the tampon. It finally remained for Vulliet to demonstrate that the uterine cavity could be greatly enlarged by the gradual use of a tampon of antiseptic cotton, and that by its aid one was enabled to treat the various diseases of the endometrium and uterine muscle with a convenience and success which had previously been unknown, or at any rate unpractised.

Materials for the Tampon.—The object of the tampon is, primarily, dilatation. This may be effected by any material with which the uterine cavity can be filled. But the presence of a foreign body within the uterus excites secretion; hence two conditions are pre-requisites in the tampon material—it must be aseptic and it must be absorbent. The imbibition of the secretions of the endometrium by the tampon increases its volume and its dilating power and at the same time favors the absorption of poisonous material; hence the necessity of absolute certainty that the tampon material be aseptic, and that the tampon be not retained too long. Of all the substances with which the uterus may be tamponed, there are but two, so far as I know, which commend themselves for general use—absorbent cotton and gauze. Absorbent cotton imbibes the secretions of the uterus with great avidity and quickly becomes converted into a hard, firm mass, which may become painful and irritating in a very short time. Nevertheless, it is readily introduced, can be adjusted with great compactness, and is highly approved by many writers, notably by Vulliet, whose credit it was, as already remarked, to advocate the persistent and extensive dilatation of the unimpregnated uterus. Preferable to absorbent cotton as a tampon material, at least in my opinion, is antiseptic gauze, which has all the merits of absorbent cotton and none of its objections.

Introduced in narrow strips, from twelve to eighteen inches in length, it is readily adjusted, adapts itself to the shape of the uterine cavity, absorbs secretions readily, does not become hard like absorbent cotton, and is more readily removed. Either the plain sterilized gauze may be used, or gauze which has been prepared with iodoform, carbolic, boric, or salicylic acid, and it frequently happens that it may be retained several days without acquiring the odor of decomposition.

Conditions in which the Tampon is Indicated.—The gauze tampon is equally indicated for the impregnated and the unimpregnated uterus. The conditions may be tabulated as follows:

I. The impregnated and puerperal uterus:
   1. During pregnancy.
   2. During parturition.
   3. Post-partum either at term or prior to it.

II. The unimpregnated uterus:
   1. For exploratory and operative purposes.
   2. For the relief of hemorrhage.
   3. For endometritis.
   4. For the relief of stenosis.
   5. For the drainage of accumulations within the tubes.

I. The Impregnated and Puerperal Uterus.—1. *During Pregnancy.*—There are many conditions associated with the impregnated uterus which have heretofore been treated, and with fair success, by tampon of the vagina, the pressure of the tampon being the efficient agent. This method, however, is often indirect and troublesome, and will eventually be superseded by the more logical and effective tampon of the uterus. Of course there are cases in which a tampon of the vagina will be preferable, and yet others in which both uterus and vagina may be tamponed with advantage. Tampon of the uterus is indicated when an abortion is imminent or is necessitated. It is simply a substitution of means. Instead of a bougie or tent a tampon of gauze within the cervix, or within the corpus, if necessary, will bring on the desired uterine contractions and facilitate the emptying of the organ. On the other hand, a light tampon within the cervix, with a moderate tampon of the vagina, will in some cases avert an abortion, checking the hemorrhage and permitting the pregnancy to continue. No fixed rules for action in such cases can be given; one must exercise his discretion according to the situation. The wounding of the uterus, which so often occurs in induced abortion by the use of instruments of various kinds, may usually be avoided when the tampon is used.

2. *During Parturition.*—A slowly dilating uterus in the first stage of natural labor is often one of the most vexatious conditions, especially with primiparæ, for both patient and physician. In such cases an uterine tampon is of great value. Its use requires judgment and a certain degree of skill, for the soft uterine tissue may be readily torn, or undue violence may be shown to the organ in its insertion. It is best introduced with the patient in Sims's position, the uterus being steadied with a volsella, and the narrow strips of gauze pushed as high as the lower

pole of the advancing fœtus. As labor progresses the tampon will be extruded into the vagina, and it should be at once removed, as its function has been accomplished.

3. *Post-partum, either at Term or Prior to It.*—When Dührssen suggested the tamponade of the uterus for post-partum hemorrhage, his proposition was received with incredulity, almost with ridicule. To tampon effectively a bleeding, viciously inert uterus is indeed an operation for which one is seldom prepared. The quantity of gauze which can be stuffed into such an organ is almost unlimited, and there is no time to send for supplies when the emergency is present. But one can always carry half-a-dozen rolls of sterilized gauze bandages, three or four inches wide, and, if this is insufficient, clean pocket-handkerchiefs, or strips from napkins or pillow-cases, are usually available for such a crisis. Of course there must be no suspicion of dirt about anything which is introduced into the uterus, and the mass must be removed at the earliest practicable moment. This operation has proved a life-saving measure in so many instances that it must now be regarded as one of the recognized expedients in severe post-partum floodings.

In hemorrhage after abortion the intra-uterine tampon will be found quite as effective as in the similar accident at term, and the operation in the former case may usually be done with more deliberation and precision than in the latter. In cases in which there is septic matter or a suspicion of septic matter within the uterus after labor or abortion, the intra-uterine tampon will sometimes be of service. The statement is made thus cautiously because in such cases curettage and irrigation have a field which will sometimes be adjunct to the tampon and sometimes will take its place. The possibilities which the tampon has for usefulness in this class of cases are very great, and I can speak with much satisfaction and assurance of the valuable aid which it has rendered me in my practice. The usefulness of the tampon may also be mentioned in cases in which the uterus contracts imperfectly or irregularly after labor or abortion, a condition which is commonly known as subinvolution. The tampon stimulates such uteri to contraction, relieves the turgid veins, effects good drainage, and may prevent protracted or even serious disease.

II. The Tampon in the Unimpregnated Uterus.—Useful and sometimes invaluable as the tampon is during pregnancy and the morbid conditions which attend and follow it, it is equally valuable for many conditions which are unassociated with pregnancy.

1. *For Exploratory and Operative Purposes.*—In the presence of intra-uterine neoplasms, whether benign or malignant, dilatation is always necessary prior to operation, and exploration will frequently decide what the condition is, and whether an operation is practicable or advisable. Such dilatation may often be effected rapidly by means of the powerful steel dilator of the Sims, or a similar, pattern. But there are cases in which such violent treatment may be inadvisable, and in these the desired effect may be obtained more gradually by means of the tampon. The field which has heretofore been occupied by the uterine tent is destined to be reserved for the tampon. In those cases in which the uterus is to be opened from the abdominal cavity or to be extirpated, the danger of sepsis from its interior may be entirely anticipated by a preliminary tampon, and in those cases in which tumors have been removed from the wall of the uterus, which have so often proved fatal because of deficient drainage, the value of the tampon will be inestimable. It is a singular fact that so useful an adjunct for such operations has so long remained unappreciated.

2. *For the Relief of Hemorrhage.*—The indications for the tampon to relieve uterine hemorrhage are many, and doubtless some which might not be deemed valid by the majority of the profession at the present time, will be so considered in the near future. Among such indications may be mentioned profuse menstruation in the feeble and anæmic, hypertrophy and inflammatory conditions of the endometrium, malignant disease of the cervix or corpus, intra-uterine tumors of all descriptions, uterine congestion accompanying disease of the adnexa, retention of the products of conception, etc. The profuse menstruation of the feeble and anæmic, which has so long been treated by the profession with nauseating drugs, or with expectancy, that is, with a confession of helplessness, should no longer subject us to reproach. Does not nature sometimes shame us by plainly teaching that the rational method is to check such loss of vitality when she checks the menstrual flow in connection with some of the wasting diseases? The wonder is that such losses can be so long tolerated by those who suffer them, and who wait in vain for the relief which is promised them—in time. Tamponade of the uterus in the unmarried, especially in young girls, is an operation which a sensitive and conscientious physician naturally shrinks from, but it is immeasurably the lesser evil and should be boldly and thoroughly carried out. The necessity for the tampon in the other conditions mentioned will probably be admitted without further argument. If mistakes are occasionally made by such a procedure they will only be the exceptions proving the rule. In almost all cases it will be well to precede the tamponade by a careful curettage. With me such a procedure is a routine method, for it frequently clears up a diagnosis which may have had elements of obscurity.

3. *For Endometritis.*—Endometritis is not necessarily accompanied by hemorrhage. In the septic varieties, in endometritis accompanied with hypertrophy, with excess of glandular secretion, with inertia, and atony of the uterine muscle, the benefits to be derived from curettage, tamponade, and drainage are unquestionable and extensive.

4. *For the Relief of Stenosis.*—Unwilling as many are to admit the existence of evil arising from mechanical obstruction within the uterine canal, especially with reference to the performance of the menstrual function, the facts are against them, the facts of induction on the one hand and the theories of deduction on the other. Those who pin their faith upon clinical experience through a series of years, in a series of careful observations, may have reasonable confidence in their conclusions. The day of stems and tents for the relief of uterine stenosis is past, or rather a better instrument for the treatment of this condition is at hand in the tampon. Whether the stenosis is natural or the result of disease or traumatism, whether the condition to be relieved be sterility or dysmenorrhœa, the indication may usually be met by the judicious application of the tampon.

5. *For the Drainage of Accumulations within the Fallopian Tubes.*—The use of the tampon for this purpose, which has been so ably advocated by Polk, does not seem to me to have so extensive an application as he thinks. I have operated upon several cases in which the dilatation of the tubes did not extend far beyond the uterine cornua, the cornua themselves being distended and the tissue friable with infiltrated pus. The tampon undoubtedly drains such cases very well, but suppose the case is not seen sufficiently early to drain thus efficiently. Suppose, moreover, that the ovaries are seriously diseased, while the abdominal ostium of the tube is still pervious, as is not infrequently the case; or suppose the tube is divided into loculi, each filled with pus, and separated from each other by impervious septa, or that the tubes are dislocated and the purulent accumulations beyond the reach of the tampon; under such unfavorable conditions, which are far more numerous than the favorable ones, temporizing or palliation may be dangerous. Therefore, while conceding the value of Polk's propositions and suggestions, the utility of the tampon seems to me here to be very limited.

Methods of Using the Tampon.—Polk's broad proposition that the tampon should be introduced with all the precautions and all the adjuncts of any surgical procedure, including the administration of an anæsthetic, is, of course, susceptible of limitations. In the tamponade of the uterus for hemorrhage post partum the urgency of the situation will forbid the deliberation and attention to details of a less serious condition, and in many other cases in which the uterine canal is patulous, the tissue soft, and the patient not unduly sensitive, an anæsthetic

will be unnecessary. I have tamponed such cases many times in office and clinic practice. For other cases the safeguards which Polk mentions are timely and requisite. As I have already said, the introduction of the tampon should invariably be preceded by curettage with the dull or sharp curette, as the case may require, by irrigation, and frequently by dilatation. Roughly speaking, if the canal is half an inch in diameter the gauze may readily be introduced. For some conditions (which will suggest themselves as occasion arises) the lateral position of the patient will be preferable for the operation; for others the dorsal. I have sometimes been obliged to change the one for the other. The lower lip of the uterus may be steadied with a volsella while an assistant steadies the upper lip. The gauze, in strips two inches wide and twelve to eighteen long, may then be passed up the fundus with long dressing-forceps until the entire cavity is sufficiently packed. The firmness with which it is to be packed will depend upon the condition for which it is used. I have not been able to use Polk's cannula to advantage, nor do I like to recommend the use of the auger-pointed introducer. The latter is too dangerous for unskilled hands, and unskilled hands must frequently perform this operation. The tampon may be retained from one to seven days, according to the indication, and it may be renewed as often as necessary. (I have kept a myomatous uterus dilated for weeks in succession.) No special rules are necessary for its extraction; it may readily be removed with long dressing-forceps. With regard to contra-indications the tampon may be so modified, as to quantity, firmness, and duration of retention, that I am unable to conceive of the impropriety of its use in any case in which intra-uterine treatment is admissible. Combined with the principle of drainage and the use of the curette it forms one of the most powerful and efficient means in uterine therapeutics. *Andrew F. Currier.*

INTRA-VASCULAR AND SUBCUTANEOUS INFUSIONS OF BLOOD AND OF SALINE SOLUTIONS.

The treatment of extreme conditions of exsanguination, whether from the direct and immediate loss of a large amount of blood by sudden hemorrhage, or from the effects of rapidly exhausting disease, has long been the subject of careful study on the part of skilful practitioners, and of elaborate and protracted experimentation by the most able and diligent observers. Such an alarming loss of blood is so terrifying, the degree of prostration is so profound, the shock to the system is so great, that few of the emergencies of professional life appeal more strongly to the sympathy of the physician, or urge him to greater exertion to ward off the fatal termination which must speedily occur if aid to the sufferer cannot be promptly rendered and efficiently applied. In the greater number of accidents and injuries followed by hemorrhage, it is possible to control the loss of blood by the adjustment of a tourniquet, by occlusion of the lacerated vessels by means of a ligature, by compression of the bleeding vessel by direct force applied over the seat of the injury, or by acupressure or other appropriate means. These means are not, however, applicable to many cases of bleeding, such as post-partum hemorrhage, secondary hemorrhage after amputation, and the accidental hemorrhages attending certain of the febrile diseases to which the human organism is susceptible—*e.g.*, typhoid—or the purpuric condition, or in cases of hemorrhagic diathesis, or in certain organic affections of the internal organs, such as ulcer of the stomach, cancer of the alimentary tract, occasionally tuberculous ulcerations of the intestinal wall, and other analogous conditions, which at times present themselves.

From the nature of the case, all patients with sudden and alarming hemorrhage must be considered as cases of the gravest emergency, and any treatment applied for the relief of the patient must possess certain special advantages, chief among which must be its universal and easy procurement and simple preparation; and in addition to these it must be harmless in its relations to the tissues or organs with which it may come in contact during its presence in, or action upon, the system.

F. P. Henry and Alfred Stengel publish in Sajous's Annual (1892, vol. ii., E., p. 16), a paper in which Thompson reports twelve cases of acute anæmia, such as those due to hemorrhage after labor, operation, etc., treated with sterilized solution of sodium chloride. Of the twelve cases, eight were treated by intra-venous injection, two by intra-venous and intra-peritoneal, and two by intra-peritoneal. Four recovered and eight died. Thompson regards the intra-venous the best method, because, when the heart is weak, solutions injected subcutaneously may not be absorbed, and because the action is more prompt. His experience would lead him to condemn the intra-peritoneal injections. Injections of saline fluids prolong life, but must be followed by injections of defibrinated blood. The sugary solution of Landerer has no special merit. Holmes, from studies of injections in acute anæmia, draws the following conclusions: 1, Auto-transfusion should be done first; 2, then infusion of large quantities of saline solution; 3, immediate intra-vascular injection of salt solution should not be practised; 4, secondary intra-peritoneal or subcutaneous injection of blood, when there is dangerous anæmia, is a conjectural matter, but should not be practised until reaction occurs; 5, immediate subcutaneous injection of blood is problematical; and, 6, the rotary surgical pump is the best apparatus. Several of these conclusions are now antiquated.

Marshall experimented with rabbits to study the effect of injections of mixtures of defibrinated blood and sodium chloride, and found, after a week, restoration of the number of corpuscles, and after three weeks, of the hæmoglobin. Stahle obtained good results from Landerer's sugar solution, as did Weber and Frank with simple salt solution. Weldon thinks that blood-transfusion has fallen into undeserved neglect, because dissimilar bloods were employed, and therefore untoward results obtained. Castellino speaks favorably of injections of 14 to 16 fluid ounces (420 to 480 grammes) of a three-quarters of one per cent. solution of soda. Lapine advocates the introduction of goat's serum directly into the veins. He uses about 50 c.c. (1¾ ounce), and has found no evil consequences, though such might be feared theoretically. He suggests that possibly the introduction of the serum of non-tubercular animals may prove useful in the treatment of tuberculosis. It is noticeable that in this somewhat extended review, no suggestion is offered as to the temperature of the solution or of the blood which is to be injected into the vascular system of the patient. In the earlier attempts to replace the blood lost by the system, it was supposed that the blood of the human organism, or that of only a few animals, could be utilized for this purpose. After this operation it was found that accidents of peculiar kinds were apt to occur, such as the coagulation of the injected blood in the vessels, this often inducing embolism, or thrombosis. Defibrination of the blood was then substituted for immediate transfusion, in which the blood was whipped with straws, and the fibrin thus collected upon them was in this way removed. The remaining fluid, supposed to be normal blood, minus only the fibrin, was then injected into the vessels. A certain number of the patients survived this procedure, but the dangers from the introduction of air into the circulation, of septic infection of the blood in the processes of preparation or otherwise, together with the peril attaching to instruments and to hands which are not aseptic, have led most practitioners to abandon this mode of treatment of sudden and alarming hemorrhage.

Among the procedures which have proved the safest and best, and which should certainly be employed in preference to the more complicated and elaborate methods, is the infusion of *hot saline solutions* into the vascular channels; thus adding to the bulk of the circulating fluid, and relieving the heart from the danger of sudden and fatal collapse. We now know that as good, if not better, results are reached by injecting warm saline-alkaline water as by transfusing blood. "Aside from the obvious dangers—clotting, embolism, sepsis, etc.—attend-

ant upon the use of any kind of blood, we now know that blood-cells other than human are broken down and disintegrated almost at once within the human body; and in consequence, a great mass of detritus is thrown upon the organs having charge of metabolism of tissue, threatening to overwhelm them with work. Even human blood-cells are probably so destroyed, though more slowly, when transferred into another body than that which gave them birth. What seems needed is only some unirritating fluid, which can supply the lacking volume within the heart and vessels; that is, to give to the heart a sufficient amount of some harmless current running through its chambers to excite systolic action. If this is done, and done promptly, at the right temperature, before the patient suffers too much from the shock caused by sudden and extreme anæmia, it is wonderful how large a loss of blood may be sustained; and how rapidly, as if by magic, nature supplies multitudes of new red blood-cells to supply those which have been lost."[1]

The following quotation from William Hunter (*British Medical Journal*, August 10, 1889, p. 309), is of interest in this connection: "After the greatest loss of blood in animals a sufficient number of red corpuscles always remains in the circulation to carry on respiration, provided that the circulation is maintained. In animals, after the loss of half to two-thirds of the total quantity of blood in the body, the number of corpuscles per cubic millimetre may be found as high as 3,000,000 or 4,000,000. The absolute loss is great, but the relative loss is slight, and is of little importance. The animal's health is in no way injuriously affected by the loss. . . . In man, a loss of blood can never be so great as in animals; syncope occurs earlier. Transfusion of blood is, therefore, never required for the purpose of supplying red corpuscles to carry on respiration after sudden loss of blood, in a patient previously healthy. The immediate source of the danger in such cases is not the want of red corpuscles, but the disturbance of the relations between the vascular circulation and its contents. . . . It is remarkable how slight the disturbance may be in cases, for example, of pernicious anæmia, in which the red corpuscles may be reduced to the extent of ten per cent., or even less, of their original number. I have observed cases in which the number of corpuscles was as low as 500,000 or 600,000 per cubic millimetre, instead of 5,000,000 as in health; the respirations never rising above 20 per minute, and the breathing, during quietude, being perfectly natural."

In cases in which the loss of blood is not immediate, as in conditions of great prostration from exhausting disease, or in pernicious anæmia and kindred diseases, the introduction of saline solutions into the connective tissue of the body, whence it is rapidly and easily absorbed into the systemic circulation, has been followed by most gratifying results. It would seem that the presence of a large amount of circulating fluid within the vascular channels, must exercise a stimulating influence upon the cardiac muscle, and possibly upon the tissues at large, with the result of invigorating the entire body. This application of *hot* saline solution has not, however, had the extensive use which has attended the intra-vascular injection of saline liquids, at bodily temperature, and its beneficent effects are not so well known.

Of course, if one had abundant time in which to prepare it, the best saline-alkaline fluid would be one identical in its components and their proportionate quantities with blood-serum. Most surgical text-books give a formula more or less approaching this. Of late it has been recommended by Ludwig, of Leipzig, to add to our saline-alkaline water a little sugar; this being a natural ingredient of the blood. Simplest of all, and so far as we can see, practically about as good as the most complicated of these formulæ, is simple warm water plus a little table-salt. It has the great advantage, too, of being always at hand when wanted. The best proportion of salt is six parts in one thousand parts of water, or about the density of blood-serum. This would be, roughly estimated, a heaped teaspoonful in a quart of warm water. The water should be first boiled, for aseptic reasons. We must never forget the salt. Such an omission would be fatal. Pure water, devoid of sodium chloride, when injected in any considerable amount, will at once dissolve out of the blood-cells their hæmoglobin, and thus promptly kill the patient.

Dr. F. C. Shattuck, in "Hare's Therapeutics," Vol. I., p. 780, has recently contributed to our latest knowledge in relation to transfusion and infusion, an article which is so carefully weighed in its estimate of the worth of these procedures, and so fair in its judgment, that I take the liberty to transcribe a portion of it in this connection. He says, "It is estimated that a person can stand a single blood-loss of at least one-third of its total volume without a directly fatal result; perhaps with a surprisingly rapid recovery.

"If the patient does not show signs of rallying from the collapse following hemorrhage, the question naturally arises of artificially supplying, to a greater or less degree, the loss sustained.

"A simple and ready means of stimulating the circulation is the application of heat, internally by a rectal injection of a quart of warm saline solution; externally, by hot bottles; some form of alcohol being given by the mouth if the patient can swallow. Or a sterilized solution of common salt, of 0.06 per cent., or 0.07 per cent., can be thrown into a vein, into the subcutaneous tissue, or into the peritoneum. It has been, and is still maintained by some, that such a saline solution is just as potent to save life as is the transfusion of pure or defibrinated blood, while it is free from some of the dangers incident to the last procedure. There are numerous cases recorded in which the saline solution seemed certainly to save life, though it is possible to assert in these that recovery would have ensued without its use. The last word has probably not been said as yet on this question. For intra-venous injection of defibrinated blood, or of a 0.05 per cent. or 0.06 per cent. solution of salt, all the apparatus required consists of a glass funnel, some rubber tubing, and a cannula; the rapidity of the flow being regulated by raising or lowering the funnel. According to Mayette, if the median basilic vein be selected for infusion, the amount should be about a fluid ounce per minute, though not much harm is likely to arise if ten ounces be injected in six minutes. This should generally be the maximum, except in cases of extreme urgency, in which the relative emptiness of the vessels is the chief source of danger. The same simple apparatus is also sufficient for the subcutaneous infusion of salt solution, from 500 c.c. to 1,000 c.c. (from 17 to 33 ounces fl.) may be injected under the skin of the back or in the axillary region, absorption being aided by gentle massage. Should the skin become too greatly distended, a second injection may be made in some other locality. This method of rapidly making up a deficiency in the quantity of the circulating liquid is free from danger, can easily be done without trained assistance, and in many cases in practice has been successful."

Ziemssen has largely practised another method which seems to be at least safe—namely, the substitution of defibrinated human blood. Its first results were not satisfactory, but after an interval of about ten years he has lately resumed his work in this line, and has now so perfected his technique as to avoid all undesirable effects and obtain marked benefit. Strict antiseptic precautions are observed throughout the operations of drawing and injecting the blood, which is done under the skin of the thighs. He uses a syringe containing 25 c.c., the contents of which are thrown slowly into the tissues, while an assistant, with hands well anointed with vaseline, puts his "full strength" into the massage of the part, so that the blood is diffused widely and thus put into a favorable form for rapid absorption. From six to sixteen syringefuls are injected at a sitting, the patient being under anæsthesia, as the injection and the massage are alike painful.

In attempting the operation of infusion, certain precautions against septic infection should be preserved. These relate to the apparatus which is used as well as to the vessel holding the liquid itself. If the instrument be

a hypodermic needle, after the wire is withdrawn from the canal of the needle, this should be cleansed by forcibly passing several syringefuls of boiled water through it, and then holding it above the flame of a lamp or gas-jet, until the water contained within the hollow needle is transformed into steam and issues as such from the end of the needle. The needle may then be considered aseptic. The rubber tube, if this is used, should be subjected to thorough disinfection by some efficient germicide, and may remain in the solution until wanted for use. If a common Davidsou syringe is used it should be most carefully disinfected, as this instrument is exposed to unusual dangers from septic infection.

A very simple and perfectly efficient plan of disinfection is to fill the syringe, and hypodermic needle, or the cannula, with boiling water, and then to immerse and boil them in water for a few minutes.

Previous to operation, the place selected for the introduction of the needle should be thoroughly washed, and subsequently scrubbed with some form of antiseptic solution. The hands of the operator, as well as those of his assistants, should also receive the necessary cleansing appropriate to a surgical operation. The solution to be injected should consist of freshly boiled water, preferably distilled water, in which has been dissolved common salt (sodium chloride), in the proportion of 0.06 per cent. or 0.07 per cent., and which has then been allowed to cool to the required temperature. Most authorities assert this to be anywhere about 100° F. There is reason to think that a much higher temperature, as first pointed out and insisted upon by Professor Dawbarn, of New York,[1] is to be preferred on account of the added stimulation from the elevation of the temperature of the liquid as it comes in contact with the visceral organs in which the vitality is reduced from the loss of blood, and in which there is also greater radiation from the surface and no corresponding rapid production of heat in the body. It is a noticeable fact that in cases of extensive hemorrhage there is always a feeling of chill on the part of the patient, and that the surface of the body is covered with a clammy and decidedly cold sweat. The infusion of *heat*, as well as the increase of volume of fluid in the circulating organs, may therefore be considered as a distinct advantage, and is undoubtedly of positive benefit in cases of extreme danger.*

Transfusion of blood has been urged as a remedy in the coma of diabetes mellitus by Dieulafoi,[2] but the measure has been found to be practically of no advantage, while the dangers and difficulties are almost of themselves sufficient reason for its abandonment, except possibly in institutions where the apparatus and necessary assistance can be readily procured. It need hardly be added here, that blood-transfusion, either mediate or immediate, has now been dropped by almost all surgeons (Dawbarn). The results so far obtained do not warrant us in believing it to be a measure that can in many instances enable us to save from death patients who have become comatose. The use of such injections has, however, in some cases, apparently been the means of cure, while in others it has been of decided benefit, although not completely successful. Dickinson reports a very interesting case in which he employed the method with apparent benefit. The account is chiefly of interest from the fact that after the injection the patient regained consciousness for a time, and that during thirty-two hours, four hundred and fifty-six ounces of fluid were injected. In his opinion the best site for the operation is the prominent vein upon the instep, the tissues there being easily dissected and the vein hooked up, while its distance from the heart insures a more perfect admixture of the solution and the blood-column before they reach the heart and the medulla. The solution should be freshly prepared from boiled and filtered or distilled water, to which has been added a drachm and a half of sodium chloride and fifteen grains of sodium carbonate to each quart of fluid used. The fluid should be warmed to 100° F. and then injected slowly by means of gravity pressure, the reservoir being held at a height of three feet above the cannula. The latter should be of about one-sixteenth inch bore. Professor Dawbarn urges, upon physiological grounds, that the salt-water should be *very hot*, not less than 120° F., which is as hot as the hand can possibly bear. It was shown in his kymographic experiments that no harm could result from less than forty degrees hotter than this; on the contrary, the stimulant effect of the hot water on the heart, and also upon the unstriped muscular tunics of the vessels in restoring their lost "tone," was almost magical. In Dickinson's cases above mentioned, there were added to the water potassium chloride, and the sulphate and phosphate of sodium. Alkalies may also be administered by the mouth, but they are not in this way so rapidly utilized as by intra-venous injection. Struempell recommends the subcutaneous injection of ether or camphor, with lukewarm baths and douches.

The new and simple technique which Dr. Dawbarn has applied to the operation of infusion of salt solution, "involves no cutting whatever, no searching for a collapsed vein, no freshened knowledge of anatomy, no tying in of a cannula, no cannula at all, in fact. All the appliances needed are such as are likely to be right at hand (it can be reasonably assumed) in nearly every instance. The instruments are, an ordinary Davidson syringe, and an ordinary hypodermic needle—large size preferred, though this is not essential. Even if the patient be pulseless at the wrist, we can almost to a certainty feel the femoral beating just below Poupart's ligament. Now, take the needle and push it directly into this artery, going slowly, until bright-red blood is seen to well up from within the needle. (As the artery here is large enough to carry a lead-pencil, the needle will not miss it, if a little care be exercised.) As soon as the arterial blood is seen in the needle, slip over its base the syringe-end, or other tube, both being filled with the hot solution, and tie a thread tightly about the syringe, securing it to the base of the needle. Now, holding the needle firmly and steadily, pump the fluid directly into the arterial current. To avoid possible pumping of air by an old or leaky syringe, make an abundance of the salt water, and keep the entire syringe, with the hand working it, beneath the surface. From the moment the determination to use the saline solution is reached, until the moment when the infusion is actually entering the blood-current, need not exceed five minutes. Should it be objected that this plan injures a very important artery, I would reply, that this is decidedly a lesser evil among those which confront the patient dying from loss of the circulating fluid. Furthermore, I have several times used this plan upon the human subject, saving the patient's life, and with no subsequent annoyance regarding the femoral artery. A further advantage of this technique is the fact, that thereby it is difficult to make the otherwise common error of throwing in the injection-fluid too fast, suddenly overwhelming the tired heart. Until one has tried it, one hardly realizes how much the intra-vascular pressure will obstruct the inward flow through the needle, even in a patient with a badly flagging heart. There will be so much resistance that it will seem as if the needle *must* be plugged with a clot or some other foreign body, so slowly, in spite of vigorous pumping, does the stream pass in; and yet in the course of half an hour's steady work, a pint or more can be made to enter.

"Whoever has noted the vigor with which unstriped muscular fibre everywhere reacts to the use of heat (for example, the much stronger and decidedly more permanent contraction which results from *hot* post-partal injections as opposed to cold ones), must believe it probable that such unstriped muscle, forming as it does a most important tunic of the blood-vessels, would be aided

* In two cases of acute anæmia recently reported by Dr. E. Sternberg, in the New York Medical Record, the *hot* infusion of salt water (120° F.) as advocated by Professor Dawbarn, was followed by complete recovery; whereas several patients treated in the same way, except that the fluid was injected at the temperature of the normal blood, died in succession. There appears to be no good reason why the injection of saline fluid should not be repeated at intervals, both for the support of the circulation and also for the purpose of aiding the elimination of excrementitious matter from the systemic emunctories.

by *hot* saline infusions in regaining its lost tone. Perhaps, too, the central sympathetic centres would feel and respond to this stimulus."

So far as the writer has been able to discover, the extremely simple and ready method of saline infusion herein described by Dr. Dawbarn—*i.e.*, using an ordinary hypodermatic needle in an artery, etc., has not heretofore been published, nor his suggestion of the value of a very high temperature in the injected fluid, instead of that normal to the body. *Albert N. Blodgett.*

[1] Arterial Saline Infusion. Dr. Dawbarn. A report of three additional cases by the New Technique, etc.; reprint from Medical Record, November 12, 1892.

INTUBATION. Since the publication of Vol. IV. of the HANDBOOK, six years ago, intubation, then in its infancy, has made rapid progress in public as well as in professional favor. In fact, its progress in some respects has been altogether too rapid for the good of all concerned, especially for that of the little sufferers from croup who are too often the innocent victims of bad instruments and incompetent operators, the two evils that beset this procedure and for which there seems to be no remedy.

Intubation is unfortunately a difficult and dangerous operation to attempt without a previous training on the cadaver, and but few of those who practise it have had such training. It is difficult solely because respiration is suspended during its performance, which requires that it must be done quickly, and to acquire the dexterity and educated touch necessary to do it thus quickly, and at the same time gently, requires a large amount of practice. Were it possible, without endangering life, to consume half a minute in any single attempt to locate the larynx, fix the epiglottis, and pass the tube, there would be little difficulty or danger attending the operation, but cutting off the small supply of air the patient is getting—when the operation is necessary—for even one-third of this time, is not always safe in bad cases.

No amount of skill in the performance of other operations affords the least aid to that of intubation. The most accomplished surgeon or laryngologist is therefore no more competent to do this operation without the practice referred to above than the merest tyro in these arts.

The laryngologist educates his sense of sight while the intubationist requires an educated touch combined with manipulative skill, a sufficient degree of which can be acquired on the cadaver to insure, in the performance of intubation, safety to the living.

The following case, reported by Dr. G. Hunter Mackenzie (Edinburgh *Medical Journal*, February, 1892), is a good example of many that might be published but are not: "Case X., girl aged two years, under the care of Dr. Henry Hay, February 3, 1891. Diphtheria of pharynx and larynx. At 11.30 A.M. the pulse could not be counted and great inspiratory dyspnœa was present. Intubation was at once performed, with immediate and marked improvement to the breathing and strengthening and slowing of the pulse. February 4th, the child has breathed freely all day and is apparently going on well. She had slept well during the night. Brandy is being freely administered, a moderate degree of difficulty in swallowing is present. February 5th, the child continues to do well. At 4 P.M. I considered it advisable to remove the tube, which had been forty hours in the larynx, and this I tried to do with the assistance of the child's father. The process of gagging and the insertion of the extractor, along with some struggling on the part of the little patient and some difficulty in locating the blades of the extractor inside the very small tube, appeared to completely exhaust the patient, and induced a condition of death-like collapse. Artificial respiration was immediately resorted to and produced a partial revival only, for the child never returned to her former condition. She died a few hours afterward without a recurrence of the symptoms of obstructed respiration."

The fatal result in this case was undoubtedly due to apnœa from prolonged attempts to remove a tube from the larynx of a child free from dyspnœa at the time the operation was begun. How much more liable is this accident to occur either in the introduction or removal of a tube when the dyspnœa is extreme! In unskilful hands a fatal result from this cause is not by any means rare. Yet there are many who claim that every practitioner should be prepared to intubate in case of emergency.

Any immediate danger to life attending the introduction or removal of a tube from the larynx, excepting cases moribund at the time, is chargeable to the operator and not to the operation. Cases very difficult to intubate are met with not unfrequently, owing principally to the engagement of the distal extremity of the tube in one of the ventricles of the larynx or in a subglottic stenosis, but the skilful operator, knowing the cause of the obstruction, knows also how to overcome it.

The most convincing proof of the popularity of intubation as compared with tracheotomy, is found in the large individual experiences that have been accumulated in the short space of time that has elapsed since the introduction of this operation. Dr. F. E. Waxham has recently reported four hundred and twenty-one cases intubated by himself. Dr. Dillon Brown has also passed the four hundred mark, and the author is approaching it. Over twelve hundred cases by three operators in a few years; and many others have passed well into the second hundred.

Individual experience with tracheotomy, on the contrary, with very few exceptions, is comparatively small, Dr. Jacobi being probably the only tracheotomist in this country who can number his cases by hundreds.

In a recent discussion of intubation versus tracheotomy at the New York Academy of Medicine, Dr. L. S. Pilcher, a well-known tracheotomist of Brooklyn, reported sixty-six tracheotomies as the outcome of seventeen years of active professional life, while Dr. McNaughton, from the same city, has intubated over one hundred and forty cases in five years. This difference is not due to any greater prevalence of croup in recent years than in the past, but to the fact that the people, especially of the poorer class, among whom this disease principally prevails, would not tolerate the cutting operation except in a small percentage of the cases.

As far as private practice is concerned, the comparative merits of the two operations in saving life constitute therefore a subject of scientific rather than of practical interest.

Diphtheritic, fibrinous, or membranous croup, with rare exceptions, is the only form of acute stenosis of the larynx in children that demands surgical interference, and this disease is so complex in its nature and is attended with so many elements of danger, independently of the laryngeal stenosis, that no brilliant results can ever be expected from any mechanical method of treatment. The principal cause of the great mortality after both intubation and tracheotomy, is the extension of the disease to the bronchial tubes where surgery cannot reach it. Then come catarrhal pneumonia, systemic poisoning, nephritis, and paralysis, all of which may be combined in the same case, but any one of which alone is sufficient to produce a fatal result.

For a description of the intubation instruments, with illustrations and method of operating, see Vol. IV., page 419, of this HANDBOOK. The only material difference in the construction of the tubes since the article referred to was written, consists in making the distal extremities somewhat bulbous, in order to prevent them from engaging in one of the ventricles of the larynx, the usual starting-point of a false passage. In the article referred to, the production of a false passage by forcing a tube through one of the ventricles and into the cellular tissue of the neck underneath the skin was barely mentioned as an accident unlikely to happen, but I have since learned from various sources that it is not at all uncommon in the hands of beginners; hence this modification in the form of the instrument, which renders the penetration of the tissues almost impossible.

Almost all the other accidents attributed to the operation of placing a tube in the larynx are due to the same cause, viz., want of skill on the part of the operator. Pushing membrane down before the tube is far more curative than dangerous, because this membrane, if detached above, and if also free below the partial or complete cast of the trachea, is easily expelled. If the pseudo-membrane is anchored below by extension into the bronchial tubes, it is difficult to get rid of it through the natural passages, even with the aid of the short, large-calibre tubes devised for this purpose. In all the cases in which casts of the trachea with numerous bronchial branches attached have thus been gotten rid of, death has resulted from reproduction or still further extension of the disease, and the same result would follow its removal by means of secondary tracheotomy.

A gradual obstruction of the tube may occur from the scanty tenacious secretions that usually accompany a high temperature, especially if associated with occlusion of the nostrils and mouth-breathing, which can be prevented by keeping the inspired air moist by means of sprays, steam, or the frequent administration of mild alkaline solutions, such as Vichy, lime-water, etc., some of which (the patient being in the upright position) will then enter the tube.

The only danger worthy of serious consideration while a tube remains in the larynx, and one which cannot always be guarded against, arises from loose membrane in the lower portion of the trachea which closes like a valve around the distal extremity of the tube and obstructs expiration almost exclusively. The only absolute safeguard against this accident is to remove the tube and attach a thread to it whenever loose membrane is detected at the point indicated, which can always be done if the child be induced to cough. It is, in fact, the best plan, for those who have had but little experience with the operation, to have the string attached in all cases in which it is possible, as the removal of the tube is more difficult than its introduction.

The method of feeding adopted by Casselberry, of Chicago, has practically done away with the two greatest objections urged against intubation, viz., the difficulty of nourishing patients with a tube in the larynx and the possible danger of pulmonary complications from the aspiration of portions of solid or liquid food swallowed. It consists in placing the patient's head considerably below the horizontal while being fed, so that anything that enters the tube during deglutition will escape by force of gravity alone. In the upright position this can only be accomplished by the act of coughing. In young children the best position is lying on the back across the lap with the head hanging so well down that it is necessary, when the child is fed from a spoon, to reach the mouth over the nose instead of over the chin. The bottle can be given in the same manner, and when wet-nursed the child can be given the necessary inclination of body by passing its legs over the opposite shoulder of the nurse. Older children may be permitted to assume any position they wish, provided the head and neck be considerably below the level of the body.

Patience and perseverance are necessary to induce some children to adopt this unnatural position in the beginning, but they soon learn that they can swallow so much better than when they are sitting up or even lying flat, that they readily assume it.

Intubation in the Treatment of Chronic Stenosis of the Larynx.—The value of intubation in the treatment of chronic stenosis of the larynx, as well as in the acute forms, is now generally recognized, and is practised in many parts of Europe as well as in this country. Dr. C. H. Knight, of New York (*Boston Medical and Surgical Journal*, July 7, 1892), reports the case of a boy, aged ten years, in whom intubation was resorted to for the relief of urgent dyspnœa due to what was supposed to be a subglottic neoplasm or a tubercular thickening of the mucous membrane, although no disease of the lungs could be discovered. The tube was worn intermittingly for about three months, and with comfort, when it was decided to do thyrotomy for the removal of the growth. Death from general tuberculosis rapidly followed the operation. Dr. Knight comments on the slight amount of disturbance excited by the tube in the larynx and the absence of objection to its long retention.

Drs. Pitts and Brook, of the Great Ormond Street Hospital, London ("Trans. London Medical Society," December 1, 1890), report four cases of chronic stenosis of the larynx in children in whom intubation was resorted to for the purpose of getting rid of retained tracheal cannulas, one of which had been retained three and another five years. They were all originally cases of croup for which tracheotomy was performed, and were all practically cured, the cannulas having been dispensed with, but at the time the report was made two cases required occasional dilatation by means of an intubation tube.

In one of my own cases of cicatricial stenosis in an adult, of syphilitic origin, after thorough dilatation of the stricture occasional intubation had to be practised for three years before the tendency to recontraction was finally overcome.

If we take into consideration the limited amount of experience with intubation which these gentlemen must have had at the time when the treatment of the above cases was begun, it must be admitted that it was admirably managed, very few mistakes having been made. The necessary precaution of keeping the external wound open until sufficient breathing-room in the larynx was obtained to sustain life in case the tube should be expelled, was adopted in each case. This was accomplished by means of a hard-rubber plug attached to a collar similar to that on the tracheal cannula.

In one case, aged three years, the largest intubation-tube for children, or that suitable for a child of twelve or thirteen years, was used without injury, which was due to the fact that the cricoid cartilage had been divided not long before the intubation was practised, thus permitting this naturally narrow and unyielding portion of the larynx to expand and accommodate itself to the very large tube. While it is true that larger tubes can be used with safety in chronic stenosis of a non-cicatricial nature than in croup, the increase should not extend beyond two sizes. When a very small tube has to be used, as is often necessary to begin with, the upper end of the instrument should be increased in size to suit the age, and when the size proper for the age is expelled the dilated lower end alone should be made larger rather than the whole of the tube. There is no necessity for haste in the treatment of this class of cases, because the difficulty of swallowing met with in the beginning, the same as in croup, is soon overcome, and all kinds of food can be taken with ease. The gentle, long-continued pressure of a tube suitable to the age is much safer than forcing in a large one which may endanger the integrity of the cricoid cartilage.

In a boy of eight years, in whom I used a tube several sizes too large, in order to hasten the process of dilatation, there developed a cricoid perichondritis with abscess which opened externally. This promptly disappeared when a smaller tube was substituted. Sloughing of the subglottic mucous membrane and necrosis of the cricoid cartilage would undoubtedly have followed had the large tube been allowed to remain long in position.

It is important to remember that it is that portion of the larynx which is bounded by the cricoid cartilage and not the chink of the glottis that determines the size of the intubation-tubes, and that it is the high operation involving this portion of the larynx that is the cause of retained tracheal cannulas in the great majority of cases.

The difficulty of getting rid of a retained tracheal cannula usually bears a direct proportion to the length of time during which it has been retained.

Anchylosis of the crico-arytenoid articulations and atrophy of the muscles that move them, together with general shrinkage of the larynx, are the inevitable result of long-continued disuse. In the normal condition these little joints never rest, and were never designed to do so, but continue their motion with every inspiratory expansion and expiratory relaxation of the glottis, day and night, during sleeping and waking. Enforced rest in

consequence of allowing the air to enter through an artificial opening is, therefore, more disastrous to these articulations than it would be for the same length of time to any other joint in the body.

Dr. E. Schniecgelow, of Copenhagen, practised intubation in eight cases of chronic stenosis of the larynx, six of which were for retained tracheal cannulas. One of the remaining two cases was that of a man, aged twenty-four years, who as a child had contracted cicatricial stenosis of the trachea following tracheotomy; the other was one of aphonia spastica. One of the cases was lost because the external wound was allowed to close before there was sufficient breathing-room in the larynx to sustain life without the tube, and another on account of plugging of the tube by tenacious, muco-purulent secretions, the case being complicated with a purulent tracheo-bronchitis.

With ordinary precautions there should never be any danger, at least in adults, of an intubation-tube becoming obstructed from secretions, because a few vigorous coughs will expel any accumulation as long as air enough can be obtained to make this act effective, and patients should be so instructed. The use of steam or sprays aids materially in keeping the tube clear by rendering the secretions less viscid.

In adults the external wound can be kept open in many cases by wearing a small tracheal cannula with the intubation-tube, as was done in one of my own cases, both tubes having been kept in position at the same time for several weeks, the outer one being corked. When the wound involves the subglottic portion of the larynx there is not room for both.

Dr. V. Nicolai (*Bolletino della Paliambulanza di Milano*) reports five intubations in adults, in four of which it was employed for the purpose of relieving dyspnœa due to laryngeal tuberculosis, which result was accomplished. In the other case the dyspnœa was the result of an intense inflammation following the removal of a foreign body which had been long impacted in the larynx. This case proved fatal from perichondritis with suppuration and burrowing of pus as far down as the bifurcation, followed by hemorrhage, the exact source of which could not be determined. The perichondritis may have been the result of injury done to the larynx in the removal of the foreign body or of pressure from the use of too large an intubation-tube.

In chronic stenosis the same tube, if metallic, should not be allowed to remain in the larynx longer than about two weeks, on account of the irritation produced by the calcareous deposits that always take place to a greater or lesser extent on its surface. Such deposits do not occur on vulcanite tubes, which can therefore be allowed to remain for a much longer time. In croup the tube becomes coated more rapidly, and for this, as well as for other reasons, it should not be allowed to remain in position longer than a week at a time. *Joseph O'Dwyer.*

INTUSSUSCEPTION.—During the last few years some advances have been made in the treatment of intussusception by operation, and the mortality of laparotomy performed for that variety of intestinal obstruction has diminished considerably. The mortality in the article in the main work was calculated from seventy cases collected from the literature of 1873 to 1887 inclusive, and reached seventy-six per cent.

In a paper published in 1891, the writer was able to analyze a total of one hundred and five cases, and found a mortality of only seventy per cent.—a very encouraging improvement. (*Medical Record*, 1891, xl., p. 534.) The corrected table would then read as follows: (see at top of next column)—

Out of sixty-five cases in which the intussusception could be reduced, only thirty-eight died, a mortality of fifty-eight per cent. Among the children of this group, the mortality was sixty-six; among the adults, only forty-seven per cent. Of seventeen cases in which the affected bowel was resected and sutured, only two recovered, both adults. Of sixteen cases in which an artificial anus was made (with or without reduction or resection

Results of Laparotomy for Acute Intussusception.

of the intussusception) two cases recovered, also both adults. These figures show again that prolonged operations are almost invariably fatal, and furnish another argument against delay, which is the usual cause of the conditions that render operations difficult, besides being directly responsible for the fact that the majority of the patients are in very bad condition when operation is finally resorted to.

In the technique of treating the bowel when laparotomy has been performed, no new suggestions have been made for those cases in which the intussusception is reducible, unless it be Senn's suggestion (*Canadian Practitioner*, August, 1891) to prevent recurrence of the invagination by making a fold or plait in the mesentery, parallel with the long axis of the bowel, and securing it with a few sutures. The efficiency of this manœuvre can, in the nature of things, only be verified by its successful use in many cases, but that the danger is real and serious is shown by the very considerable number of cases in which relapses have occurred, even directly after reduction, whether by injections or by operation. Thus Gould (*Medical Press and Circular*, 1891, ii., p. 385) reports a case in which he operated successfully upon a patient upon whom Hulke had also operated three months previously; and Pick (*Lancet*, 1891, i., p. 1312) had a recurrence necessitating reopening the wound thirty-six hours after the first operation, the patient dying of shock finally.

The method of dealing with doubtful and even half-sloughing gut demands a few words. Recent experience has shown that the isolation method suggested by Hahn for intestinal resection and suture, consisting in wrapping the sutured portion in iodoform gauze and allowing it to lie just within the abdominal wound, or even entirely outside of the wound on the wall of the abdomen, can be applied to such cases. If perforation should occur, the escaping contents would be taken up by the gauze and conducted outward, and the peritoneal cavity would not be infected. In a case reported by the writer (*loc. cit.*) in which reduction was accomplished with difficulty and the condition of the bowel was doubtful, the suspected loop was wrapped in iodoform gauze, the ends of which were brought out of the abdominal wound, and the latter packed with the same, its lips being prevented from gaping by being drawn against the packing with temporary sutures of silver wire or coarse silk. The patient was almost moribund when the operation was performed, and died of shock, but the bowels moved before death, showing that this method can be employed in such cases without producing obstruction at the point where the gauze is packed around the bowel. If it is feared that the loop might be displaced by peristalsis, a strip of gauze can be passed around it, penetrating the mesentery at a point free from blood-vessels.

If the intussusception be irreducible, Senn (*loc. cit.*) strongly recommends anastomosis, when there is no gangrene of the sheath, if the invagination be small. If the intussusception, on the other hand, be large, he advises a preliminary resection of the intussusceptum through a

longitudinal incision in the sheath, after having secured the neck with a rubber ligature, the anastomosis being made subsequently. In either case the obstruction in the bowel is left unrelieved, but a passage is made around it for the circulation of the contents. Barker (*Lancet*, 1892, i., p. 79) appears to deserve the credit for the suggestion to remove the intussusceptum through a longitudinal incision in the sheath, but he advised it as a part of a form of circular suture, Lembert sutures being introduced around the neck before opening the sheath, and the two coats of the intussusceptum being sewed together by a few stitches through all the coats after the resection. Maunsell has lately ("Transactions of the Intercolonial Medical Congress of Australasia," 1889, p. 236) advocated a similar proceeding for all cases of intestinal resection, first making an artificial invagination of the portion to be removed. The danger of these methods lies in the liability to continued invagination, fresh portions of the gut becoming involved, and also in the possible occurrence of stricture at the point of resection. Barker lost both of the cases upon which he operated, but through no fault in the method, and states that two others operated upon according to a similar method gave no sign of stricture several months, and five years later.

Kammerer (*Medical Record*, 1890, xxxvii., p. 113) reports a successful laparotomy for intussusception in an infant only six months old, which together with Sands's case (*N. Y. Medical Journal*, 1877, xxv., p. 561) shows that extreme youth is no barrier to successful operation for this condition. Körte (*Berlin. klin. Wochenschrift*, 1892, p. 652) found an ascending intussusception in a patient upon whom he operated successfully—a variety which some suppose never to occur in the clinical form, although some cases of chronic intussusception have been reported in which this variety was found after death.

Prolapsed intussusceptions have been frequently extirpated by drawing them out of the anus until the upper limit could be reached, and sewing the layers together circularly before the intussusceptum was cut away. Until recently the sutures were passed through all the coats of the bowel at once, the surgeon inserting one finger into the lumen of the intussusceptum until normal bowel was reached above, and assuring himself by pressure between that finger and another outside, that there was no loop of bowel or other abdominal organ between the peritoneal surfaces of the intussusception, and then introducing a curved needle from without into the lumen of the intussusceptum under the guidance of the finger, and then out again, so as to make a stitch which took up a small portion of both layers of the intussusceptum. This was tied on the outside, and when the entire bowel had thus been surrounded with sutures above the neck of the intussusceptum, the latter was cut away just below the line of stitches. But a loop of bowel has occasionally been wounded in operating by this rather blind method, and, moreover, sutures thus introduced through all the coats of the bowel may be the cause of infection, leading it from the mucous membrane through the wall of the gut into the peritoneal cavity. The latter danger has compelled the rejection of all methods of intestinal suture which depend upon such stitches, and although it is true that if the sphincter were paralyzed by stretching, or were divided, there would not be quite the same danger in the rectum as elsewhere in the intestinal tract, because the intra-intestinal pressure could be reduced to a minimum, yet there would certainly be some danger, and most modern surgeons would prefer the method suggested by Mikulicz (*Wiener medizin. Presse*, 1883, Nos. 50 and 51). In this procedure the intussusceptum is drawn down until its upper limit is reached, and then a superficial incision is made on its anterior surface, and gradually deepened until the peritoneal cavity is opened, the vessels being tied as they are divided. A row of fine silk sutures is then inserted through the peritoneal coats only, like Lembert sutures, securing the peritoneal surfaces of the two layers of the intussusceptum together. The posterior half is next treated in the same way, and then the intussusceptum is removed by dividing the internal layer step by step, securing its cut edge to that of the outer ("middle") layer by sutures, taking up all but the peritoneal coat, as the incision is carried around the tumor. In this manner the peritoneal cavity is shut off before the bowel above the point of obstruction is opened, and this is a great advantage, for even if there is no fecal accumulation, it is impossible to cleanse this part beforehand. The danger of penetrating sutures, moreover, is avoided, and it is impossible to overlook any loops of bowel which may lie prolapsed between the coats of the intussusceptum.

In case of emergency it might be well to remember the excellent expedient employed in three successful cases by Weinlechner and by Hofmokl, quoted by Mikulicz. They passed a stiff tube into the intussusceptum and ligated it at its neck upon the tube with a rubber ligature, allowing the ligated mass to slough off, by which time the adhesions were complete. This would answer very well where it was impossible to command the assistance and skill necessary for the operation of excision and suture, although the danger of sepsis from the sloughing process should limit the use of the method to such cases.

B. Farquhar Curtis.

IODANTIFEBRIN. This is prepared from acetanilide by substituting iodine for one hydrogen atom. Its formula is $C_6H_4INHC_2H_3O$. It was prepared by Dr. Ostermayer, who also introduced iodantipyrin. It is a white crystalline powder insoluble in cold, but soluble in hot water and alcohol. The experiments of Dr. Ostermayer showed that it was devoid of any therapeutic action. No effects were observed that could be attributed either to the acetanilide or to the iodine, nor could either be detected in the urine after its administration. It appears that the iodine destroys the activity of the compound and that no absorption takes place.

Beaumont Small.

IODANTIPYRIN; IODOPYRIN. This compound, introduced in 1891 by Dr. Ostermayer, is antipyrin in which one hydrogen atom has been replaced by iodine. Its formula is $C_{11}H_{11}INO$. It forms in colorless, shining, prismatic needles, not very soluble in cold water or alcohol, but readily soluble in either when hot.

Iodopyrin was supposed to be a soluble combination of the therapeutic properties of antipyrin and iodine, but experience has shown that in the stomach it is decomposed by the hydrochloric acid, and forms antipyrin and iodide of sodium. The same object may be obtained by administering iodide of potassium and antipyrin. Its antipyretic effects are those of antipyrin. In typhoid fever, pulmonary phthisis, rheumatic fever, and other febrile conditions, it lowers the temperature rapidly, and lowers the pulse and respiration; at times it produces a free perspiration. The dose is from seven and a half to twenty-two grains. The value of the iodine is uncertain, as no decided benefit has been traced to it. One case of a persistent headache, thought to be syphilitic in character, is reported, in which a cure was effected in twenty-four hours. The iodine may be detected in the urine after fifteen to twenty-two grains have been given.

Beaumont Small.

IODINE TRICHLORIDE. A compound introduced by Langenbuch, of iodine and chlorine, made by passing chlorine gas over iodine. It forms a reddish crystalline powder, hygroscopic, very soluble in water, alcohol, and glycerine, and has a pungent and disagreeable odor. It is a stable compound, and will keep for a long time in powder or in solution; it must be dissolved in distilled water, as any organic matter decomposes it at once. When brought in contact with the pus and secretions of the tissues, it is at once decomposed and its constituents eliminated. It is a powerful antiseptic and bacteriacide; a one per cent. solution sterilizes cultures of the ordinary pus-producers—staphylococcus and streptococcus.

Belfield (*Medical Record*, vol. xiii., No. 3) has used it extensively in surgical practice. He considers that it combines the valuable properties of iodoform and hydro-

gen peroxide. It is a more active antiseptic than iodoform, and is more stable than the peroxide, remains longer in contact with the parts, and sterilizes all moist animal tissues as well as pus. Its disadvantages are its caustic properties when used in strong solutions, and its injurious action on instruments and clothing. It must be kept from the light and air. It has been used in various tubercular diseases and all forms of suppuration, and in all it proved of decided value. Internally the dose is one-fifth grain; it is also used by hypodermic injections of one-tenth to one-half per cent. solution, and the same solution is used for washing out the bladder, the urethra, and other sensitive mucous membranes. For irrigating wounds, a one to five per cent. solution, either alone or with glycerine, may be employed; for putrid surfaces, a five to twenty per cent. solution in equal parts of water, glycerine, and alcohol. Gauze may also be prepared by medicating with the solution. In eye affections, a one to five thousand solution is used as an ordinary antiseptic wash. *Beaumont Small.*

IODOFORM. This drug has recently acquired a reputation as an autitubercular agent, and has been extensively employed in the treatment of the various forms of tuberculosis. In chronic abscesses, disease of bones, of joints, and of the tissues about the joint, and in all forms of tubercular disease subject to the surgeon's knife, iodoform may be applied to the affected part with as much confidence in its specific and curative action as has always been placed in it in the treatment of wounds of a simple character. It is well known to be antagonistic to the growth and extension of tubercle. It checks the growth of the bacilli and counteracts the ptomaïnes and other products of their growth, and evidence is now showing that it exerts a decided destructive action on the bacilli themselves. It was shown some years ago by Sanger and Braus [1] that the bacilli of tuberculosis and anthrax were both influenced by the presence of iodoform, becoming lessened in number and weakened in virulence and infective power. Others have confirmed these facts, and among the more recent reports are the experiments of Drs. G. Troje and F. Tangl.[1] They report the result of their investigations upon the effects of iodoform, in the form of vapor, powder, and emulsion, upon cultures of the tubercle bacilli. It was found that the vapor killed the organisms after fifty days. After it had acted six days the growth was decidedly diminished, and, at the end of six weeks, had ceased. The powder, when strewn on the bacilli, rapidly checked their growth, and the culture when mixed with the powder, in the proportion of one part to fifteen, was rendered innocuous in eight days. A ten per cent. mixture of iodoform with oil or glycerine, was found to have greater destrucive properties than either the vapor or the powder. The oil proved somewhat stronger than the glycerine mixture.

During their experiments they found that the influence of the emulsion was less when a mixture of the oil and culture was injected in the tissues than when they remained outside the body. The tissues proved a suitable soil for the growth of the bacilli, and they acquired a new energy. It was also found that the bacilli, when acted upon by the iodoform, could be so weakened that only chronic forms of abscess followed their inoculation. In the cold abscess arising from bone disease and other chronic forms of suppuration, the bacilli are few in number and less active, and more readily acted upon by iodoform than the cultures outside the body, or when freshly inoculated. The conclusions they reached, as a result of their experiments, were: that iodoform is a true disinfecting agent, and that it has a direct poisonous action on the bacilli, if left sufficiently long in contact.

In addition to the action on the bacillus, iodoform also exerts a stimulating action on the diseased tissue, and promotes an active granulating surface inclined to repair. It has been shown[2] that the walls of a tubercular abscess consist of four layers: (1) a layer of thick porous tissue; (2) a layer of spindle cells in active proliferation; (3) actual tuberculous granulations; (4) necrotic and degenerated tissue. The two inner layers contain the bacilli, and these, under the action of the iodoform, disappear, and healthy granulations spring from the spindle-cell layer.

Whatever may be the influence of iodoform, clinical evidence is very clear regarding its decided curative action. In a report of two hundred and fifty-five cases over forty per cent. were decidedly improved. Other authorities claim that eighty per cent. of all abscesses may be made to disappear by this treatment, and in our own journals the numerous reports of cases in which a cure has been effected indicate the value of the drug.

To obtain the benefits of this method of treatment the remedy must be brought in direct contact with the disease. As generally followed, the abscess is evacuated and washed with an antiseptic solution of carbolic acid or boracic acid, and a ten per cent. solution of iodoform is then to be injected. The amount to be used varies greatly, from one or two drachms up to one and even two ounces having been recommended by various authorities. Bryant [2] advises the use of two or three ounces; Curtis [3] and Darling [4] find the most satisfaction by using from one to two drachms. The injections are repeated in accordance with the recurrence of the pus and subsidence of the effects of the former injection, the time varying from a few days to two or three weeks. In contrast with this mild treatment are the heroic methods of the European surgeons. Professor Billroth [5] has adopted this method of treatment since 1881, and the results have exceeded his expectations. His method is to open the abscess with a free incision, and when its contents have been evacuated the walls are rubbed with iodoform gauze, the cavity washed with sublimate solution, and then stuffed with iodoform gauze until all bleeding ceases. Before opening the abscess he uses an Esmarch bandage, which is removed after the cavity is emptied. When the bleeding has been checked the gauze is removed, the emulsion poured in, and the wound stitched. If diseased bone is present it is scraped and cleansed also. In most of the cases the operation was followed by fever, varying in degree. In the most favorable cases there is very slight fever or pain, no tension, and healing by first intention; the dressings are allowed to remain for two weeks, the stitches are then removed and dressed again for another two weeks, when a cure is complete. Generally there is sharp fever and pain, and serum escapes through the incision. In these cases the dressings are removed every few days and drainage-tubes used until serum ceases to be discharged. If recovery does not take place in five or six weeks, the operation of opening the wound and cleansing the cavity is repeated. Professor Jassinski [6] reports the result of eighty-six cases treated by aspirating and injecting with the emulsion. The results were much the same. A number healed without further interference, and others had to be opened and treated by washing and pouring in the emulsion. Fever and pain generally followed, but in no case was there any toxic action produced, although as much as one hundred and eighty grammes were injected.

In tuberculous disease in which suppuration has not taken place, the emulsion (from ten to twenty minims) is injected into the diseased tissue and made to diffuse itself by gentle massage. In enlarged glands the same treatment is adopted, and also in tubercular disease of the testes, bladder, and rectum, and in tubercular empyema.

The iodoform is prepared for use by dissolving in alcohol, or ether, or by forming an emulsion with oil or glycerine. The formula of the emulsion used by Mosetig-Moorhof, who first used iodoform for this purpose, was: iodoform, 10 parts; ol. ricini, ol. amygdalæ, āā 15 parts. This has passed through various modifications, until at present a ten per cent. mixture is very generally adopted, and oil or glycerine is the menstruum selected. The alcoholic or ethereal solutions are not so frequently employed, on account of the pain and irritation that follow their use. They are, however, more diffusible, and correspondingly more active. The more concentrated solutions, particularly the ethereal, are very unstable, iodine being set free and coloring the solution. The preparations should be recent, and the oil employed should be

sterilized. This may readily be done by boiling for half an hour. Camphor increases the solubility of iodoform, and a six per cent. solution may be obtained by using a saturated solution of camphorated oil. The use of oil heated to 100° F. will allow of more iodoform being dissolved, and this is now recommended as a more efficient way of securing a suitable solution.

There is very little danger of toxic symptoms, especially if the emulsions are used. Whenever any constitutional disturbance has occurred it has generally been in cases where the ethereal or alcoholic solution was used. No definite quantity that may be injected with safety has been determined. In some instances a few grains have caused much trouble, and in others very large amounts have been used with perfect safety. When the system is affected there is a sense of lassitude and sickness, a bad taste in the mouth, accompanied by headache, restlessness and delirium, and fever in some cases, and in others by drowsiness and collapse. Bromide of potassium is said to act as an antidote, not only as a neutral potash salt, but also by its specific bromide action. This is thought to arise from its solvent properties for iodoform. The presence of iodine in the saliva may be detected by placing in the mouth a piece of silver, when a garlic taste is immediately developed. The saliva may also be tested by mixing it with calomel. If iodine be present a canary-yellow color is produced, due to the formation of iodide of mercury.

Iodoform has been employed in the treatment of tuberculosis of the respiratory organs, but not with so much success as in the forms of tuberculosis in which it may be applied directly to the part. Its administration by the mouth was found to be very uncertain in its action, and to cause gastric irritation. This method has been replaced by subcutaneous injections which convey the drug more directly to the lung tissue and enable it to act more energetically. It is said to lessen the mucopurulent secretion and render it more fluid. It softens the hardened tissues and allows the air to permeate deeper into the lungs. Although it is not thought to act on the cause of the disease, it aids the elimination of the broken-down tissue and favors the cicatrization of the ulcerated surfaces in the alveoli. The ethereal solution, or an emulsion of sterilized oil, may be used. The dose for internal administration is one-third to one-sixth grain several times a day, or, if used hypodermically, two doses in the day will be sufficient. In tubercular phthisis it is more frequently combined with guaiacol for hypodermic injections, and in this form has given much satisfaction.

IODOL (Tetra-iodo-pyrrol). This compound of iodine may be prepared by dissolving pyrrol in alkaline water and mixing it with a solution of iodine in iodide of potassium. The precipitate is collected, dissolved in alcohol, and reprecipitated. It is also obtained by the reaction that takes place when alcoholic solutions of pyrrol and iodine are mixed for twenty-four hours. Iodol separates when the mixture is added to water.

It is a pale yellow, finely crystalline powder. It is without taste and does not possess any disagreeable odor. It is insoluble in water, and very slightly soluble in dilute alcohol. Strong alcohol dissolves one part in six; glycerine, one part in thirty-four. Iodol is very soluble in ether and chloroform. It contains about ninety per cent. of iodine. Heated to 140° or 150° C. it is decomposed with the evolution of violet iodine vapors.

Iodol was introduced in 1885 by Ciamician and Silber, as a substitute for iodoform, its freedom from any disagreeable odor being a decided advantage. Like iodoform it does not rank high as a germicide, but it has the same power of inhibiting the growth of bacteria and maintaining a surface clean and aseptic. To wounds, ulcers, and all suppurating surfaces it is applied in the same manner as iodoform, by dusting the powder on the part, or making it into an ointment with lanoline or vaseline. It may also be used in solution of alcohol, ether, or collodium. Ether, 5 parts; collodium, 50 parts; iodol, 1 part, is a favorite combination for local application. For gynæcological purposes a solution of iodol, spirits, and glycerine, 1 : 16 : 34, may be used for saturating tampons, etc. Its local use has been highly recommended for ulcerations of the nose, pharynx, and larynx, particularly when due to a tuberculous or syphilitic cause.

Iodol has been employed internally with success in conditions of the stomach and intestines accompanied by putrefactive and fermentative changes. It has been used with success in gastro-intestinal catarrh and ulceration of the mucous membrane. When its action is directed to the stomach it should be given in the intervals between meals; when it is desired to act on the intestinal canal the most favorable time for its administration is immediately at the close of the digestive process. As its constituent iodine is excreted in part by the pulmonary organs, it has been used in bronchitis, phthisis, and various diseases of this locality. In these conditions, in addition to its internal administration, inhalations and insufflations were used. In syphilis it is also recommended: in tertiary forms of the disease it has given the greatest success. It is well borne by the system, having no effect on the temperature, circulation, or respiration; iodism is of very rare occurrence. It is also thought to be of benefit in diabetes. The dose is from five to fifteen grains, two or three times a day: it should be given in wafers or pill form. Although the proportion of iodine is very large, toxic effects are very rarely noticed. The iodine is evolved very slowly, and its action is slow and gradual.

Beaumont Small.

IODONAPHTHOL-BETA (Naphthol-beta di-iodide). This derivative of iodine was introduced by Dr. Braille (*Répert. de Phar.*, November 10, 1891) as a substitute for iodoform, aristol, and other iodine compounds. It is prepared by mixing a solution containing 24 grammes of iodine and 27 grammes of potassium iodide with another solution containing 110 grammes of naphthol-beta and 40 grammes of caustic soda. There is then added a little solution of the hypochlorite of sodium corresponding to ten times its volume of chlorine. Iodonaphthol is then precipitated. It is a greenish yellow powder, inodorous, tasteless, insoluble in water, very slightly soluble in alcohol, but soluble in ether and chloroform.

It is recommended for the treatment of wounds, ulcers, and all conditions in which iodoform and other antiseptics are employed. It is applied as a powder dusted on the part affected.

Beaumont Small.

IODOPHENIN (Iodophenacetin). This compound of iodine and phenacetin was described by Dr. Scholvein, in 1891, at a meeting of the Berlin Pharmaceutical Society. It contains fifty per cent. of iodine and forms in steel-blue crystals, with an odor of iodine, and a burning taste; it colors the skin yellow. It is insoluble in water, soluble in alcohol and glacial acetic acid. Heated, or even when mixed with water, it is decomposed and iodine is set free.

Owing to the looseness with which the iodine is retained in combination, it is recommended as a useful antiseptic. Experiments show that it possesses this property in a marked degree, but also has the irritating effects of free iodine, and it is doubtful if it has any advantage over pure iodine.

When employed as an internal remedy it forms combinations with the alkalies of the intestinal canal, and, from the readiness with which iodine is given up, poisonous symptoms often follow the use of even small quantities.

Beaumont Small.

IODO-SALICYLIC ACID. A compound of iodine and salicylic acid in which one atom of hydrogen is replaced by one of iodine. It contains fifty per cent. of iodine. A *di-iodo-salicylic acid* is also prepared in which two atoms of hydrogen are replaced by iodine. It contains two parts of iodine in three of the compound. They are white, fine crystalline powders, slightly soluble in water, soluble in alcohol, ether, fixed oils, and collodion.

They possess the combined action of iodine and salicylic acid, and are said to be very serviceable antiseptics. Internally, in doses from twenty to sixty grains daily, they have proved servicable in rheumatism and have succeeded in relieving the fever and pain when the other salicylates have failed.

Sodium di-iodo-salicylate. This salt occurs in white needles, and is recommended as an antithermic and antirheumatic. It is also said to be of great value as a local application in parasitic affections of the skin. The dose for internal administration has not been determined.

Beaumont Small.

IODOSULPHATE OF CINCHONINE (Antiseptol). This compound is obtained by the action of iodated iodide of potassium upon a solution of sulphate of cinchonine, twenty-five parts to two thousand of water. It contains fifty per cent. of iodine. It is a very light, brownish powder, odorless, insoluble in alcohol and chloroform.

It is an antiseptic and is said to prove serviceable in all conditions in which iodoform and similar compounds are employed. It may be combined with powdered talcum, one part to two; or mixed with vaseline or lanoline, one part to ten.

Beaumont Small.

JAMAICA. Brief mention was made of this island in the article on the climatology of the West Indies in Vol. VII., but owing to its increasing importance as a health resort and as a winter residence for invalids and others from the United States and Canada, it has been thought advisable to give a rather more detailed account of its climatic and other advantages in the present volume.

Jamaica, a British colony, is an island in the Caribbean Sea, lying between 17° 43′ and 18° 32′ North latitude, and 76° 11′ and 78° 20′ 50″ West longitude. It is about 90 miles south of Cuba, nearly 5,000 miles from Southampton, and a little more than 1,400 miles from New York. It is 144 miles in length and from 21½ to 49 miles in width. The surface of the island is crumpled up into a central mountain range with numerous outlying spurs. The highest points of this range, contrary to the usual rule, are in the eastern portion, whence the surface slopes irregularly toward the west, where the only level parts of any extent are found. There is one principal range, called the Blue Mountains, running east and west through the centre of the island, and from this secondary ridges run north and south, themselves giving off other and shorter spurs in a direction parallel to the central range. The highest point is Blue Mountain Peak which rises to an elevation of 7,360 feet; Catherine's Peak has an altitude of over 5,000 feet, and there are several others, varying in height from 4,000 to 5,000 feet. The island is in general well watered, the abundance of rivers and springs in most parts giving plausibility to the generally accepted interpretation of the name, Jamaica, which is believed to have signified in the aboriginal tongue the "Isle of Springs," or the "Land of Wood and Water."

It is difficult, in a brief article of this nature, to describe satisfactorily the climate of Jamaica, as owing to the diversity of elevation and other causes, it varies greatly in different parts of the island; in some parts it is hot, in others temperate and even cool; in some it is dry in others the rainfall is very great; and indeed the only characteristic common to all the varying climates of Jamaica is equability. Thus at the sea-coast the average temperature is 78° F. (the extreme range for the entire year being only 35° F.), while on the mountains at an elevation of between 4,000 and 5,000 feet the mercury ranges from 50° to 70° F., occasionally falling, on the summit of the highest peak and in midwinter, even to the freezing-point. In the accompanying charts, compiled from the official figures in the "Handbook of Jamaica," the mean temperature is given for the city of Kingston, and this may be regarded as the mean maximum for the entire island. Unfortunately, systematic observations of the variations of temperature in the more elevated portions of the interior are wanting, but numerous unofficial readings of ordinary thermometers, taken with more or less regularity for a number of years by private individuals, show that the indoor temperature in places in the interior is on an average from 5° to 15° below the figures here given. From June, 1880, to the end of the year 1886 the readings of the thermometer were taken at eight-hour intervals, to wit, at 7 A.M. and 3 and 11 P.M., but since that time at 7 A.M. and 3 P.M. only.

During the entire period the highest temperature observed was 96.1° F., recorded on September 12, 1880, and the lowest was 56.7° F. recorded on December 4, 1887. The *absolute* maxima and minima are not given in the first table; but their averages are about four degrees above and below the maxima and minima deduced from the daily readings.

The most striking peculiarity of the climate of Jamaica is its variety combined with equability. A ride of a few miles into the hills will bring one from the torrid zone to the temperate—from an average temperature of nearly 80° F. to one of 65° or 70° F. But whatever district one may select, whether a warm or a cool one, he

will find the temperature very nearly constant, the extreme range for any one month being seldom over 25° F., while that for the entire year at Kingston is but 35° F., and in some parts of the island the excursions of the mercury are even more restricted than this. As regards humidity, also, there is the same choice of climate open to the invalid or the pleasure-seeker, who may select a place of residence with a humid or a dry atmosphere as suits best his inclinations or the necessities of the affection from which he suffers. Jamaica, indeed, enjoys all the advantages in respect to uniformity of temperature of island climates in general, while the differences in elevation and in exposure to, or protection from, the prevailing trade winds, give to it the pleasing diversity, as regards temperature, humidity, and rainfall, of the most temperate of continental climates.

In the first of the meteorological charts the rainfall is given in two columns, one for Kingston and the other the average for the whole island. There is, as a rule, less rain in Kingston than in most of the other parts of the island, the trade winds being drained of their moisture by the mountains to the north and east of the city. The heaviest precipitation occurs in the Parish of Portland, which forms the northeastern extremity of the island. There are two principal rainy seasons, namely in May and October, but there is usually more or less rain all through the summer months; in the winter season in the neighborhood of Kingston the precipitation is very light. The rain usually comes in heavy showers of only a few hours' duration, and the days during which the sun does not shine at all are very rare. It is always possible to tell when rain is coming, as it can be seen, quite a while before its arrival, advancing from the mountains, thus giving one ample time to get under cover before the downpour begins. This is fortunate for the visitor, as a wetting is one of the three things that an unacclimated person in the tropics must avoid, the other two being exposure to the direct rays of the noonday sun and to the cool night air.

The population of Jamaica, according to the census of 1891, is 639,491, an increase of about 60,000 since the census of 1881, and of 133,000 since that of 1871. The capital and chief city is Kingston, the largest and most important as well as the healthiest seaport town of the British West Indies. It is a city of 48,500 inhabitants, situated on gently sloping ground on the shores of a large land-locked harbor. The land on which the city lies is a gravel bed, and as it has a slope to the sea of about ninety feet to the mile the natural drainage is excellent. The water supply is drawn from two rivers at a distance of several miles from the city, and, as regards freedom from contamination, is above reproach.

The Myrtle Bank Hotel, pleasantly situated on the shore of the bay near the outskirts of the city, affords excellent accommodation for visitors, and there are also several other hotels and a number of boarding-houses where one may live modestly and at moderate expense. Another well-built hotel, having accommodation for one hundred and fifty to two hundred guests, is at Constant Spring, six miles from Kingston, near the foot of the mountains which enclose in the form of an amphitheatre the Liguanea plain. The hotel lies at an elevation of five hundred feet above Kingston, and from it is had a fine view of the harbor and Caribbean Sea beyond. The temperature here is uniformly ten to twelve degrees lower than that of the city. Other comfortable hotels are found in Santiago de la Vega, usually called Spanish Town, which was formerly the capital of the island, and at Moneague, a charming spot in the Parish of St. Ann, on the northern slope of the central mountain range. Mandeville, a beautiful little place in the hills, celebrated for its delicious oranges, is a favorite resort for Jamaicans from Kingston and other coast towns who may feel the want of a change of air and scene. There are a hotel and several boarding-houses here, but intending visitors must take the precaution to apply in advance if they would be sure of being well suited. Among the coast towns on the north side of the island, Lucea, St. Ann's Bay, and Montego Bay are the most important from the point of view of the tourist and the invalid. In these and the other towns of the island visitors may find accommodation at various boarding- and lodging-houses; about which, however, it would be wise to inquire before making a selection, as they are of varying degrees of excellence and the reverse.

At Port Henderson, on the southern shore of the island, at the entrance to Kingston harbor, there is a saline calcic spring which is said to possess tonic properties of no mean order and is much resorted to as a bath by convalescents and others from the neighboring districts. There is also a good beach for sea-bathing. There are several buildings here in good order, but the accommodations are not extensive. The place can readily be reached, however, by a steam launch from Kingston in forty-five minutes. No analysis of the water of the spring has ever been published.

The diseases for the climatic treatment of which Jamaica is well suited are bronchitis, fibroid phthisis, incipient pulmonary tuberculosis, catarrhal affections of the respiratory passages, Bright's disease, rheumatism, various forms of dyspepsia, and nervous prostration. All parts of the island are naturally not suitable for the treatment of all these varied affections, but for each one a locality exists where the patient can find the climate especially adapted to the necessities of his particular disease. Respiratory affections especially do well in this mild and equable climate, as may be judged from the records of one of the life insurance companies doing business on the island, which show that the company lost but one life from diseases of the respiratory organs (bronchitis) during a period of thirty-five years. Patients suffering from these troubles are relieved in almost any part of the island, although there is even here a choice, as cases with scanty expectoration are most benefited in those districts where the atmosphere is most laden with moisture, while those in which there is free or even profuse secretion are more quickly relieved in the neighborhood of Kingston and other parts where the humidity of the air is at a minimum. Patients with nervous prostration receive more benefit from a stay near the seashore than they do in the uplands, and the same is in a measure true of dyspeptics, especially of those in whom the gastric trouble is partly nervous in its origin. Sufferers from Bright's disease do well, as a rule, in all parts of the island, except possibly in the most elevated regions, where in the winter months the thermometer is apt to fall a little too low after the sun goes down, and where, especially on the northern slope, there is at times rather too much rain to be agreeable. The same remarks apply also in the case of rheumatic patients, but the latter would do well to take a course of the waters at one of the numerous mineral springs, of which a few words may be said in closing this article.

There are several medicinal springs in Jamaica, some thermal and others cold, which possess therapeutic properties of no little value, and which are deserving of more careful study by balneologists than they have hitherto received. The most important of these, or at least the best known and the only ones at which passable accommodations for visitors are as yet provided, are the Bath of St. Thomas the Apostle, about a mile from the town of Bath, in the Parish of St. Thomas, the Jamaica Spa, at Silver Hill, in St. Andrew's Parish, and the Milk River Bath at Vere, in the Parish of Clarendon. The first of these is a thermal sulphur, the second a chalybeate, and the third a thermal saline water. The table on the next page, extracted from a brochure on the "Mineral Springs of Jamaica," by the Hon. J. C. Phillippo, M.D., shows the results of analyses of these three and two other springs on the island. All of these springs are quite easily accessible from Kingston.

The limits of this article will not permit of a detailed description of each of these springs, but the subjoined analyses will suffice to indicate their character and to suggest their therapeutic application. The waters of one or the other of the springs are of value, taken internally and applied in the form of baths, in the treatment of gout, rheumatism, chronic bronchitis, catarrhal conditions of

the stomach and intestines, constipation from abdominal plethora, hepatic and other congestions of the abdominal viscera, amenorrhœa, anæmia and chlorosis, various forms of skin diseases, tertiary syphilitic lesions, and chronic malarial affections. The Government has made grants from time to time for the improvement and care of the buildings at these baths, but there is yet much to be desired in the matter of cuisine, bathing facilities, attendance, and other things that contribute to the comfort and entertainment of the invalid. In the absence of these desiderata they still possess the great advantage that they may be visited in the winter season, when the more pretentious and better equipped spas in Europe and the United States are closed.

There are several lines of steamers running between Jamaica and New York, Boston, and Halifax, the voyage from New York being made in from four to six days. During one season steamers plied between Tampa, Fla., and the north shore of Jamaica, and it is probable that this service will be resumed again as soon as the railroad across the island, now nearly completed, is open for travel. There is usually no lack of amusements in Kingston in the way of horse races, yachting, tennis and cricket matches, etc., and there is also a theatre where performances and concerts are given occasionally during the winter. The roads throughout the island are up to the best English standard and the facilities for riding and driving are unsurpassed. A railroad runs from Kingston in a northwesterly direction to Montego Bay, with a branch line to Anatto Bay and Port Antonio, towns on the north shore. Communication with the coast towns is had also by steamers which sail around the island once a week, leaving Kingston every Tuesday. There is frequent mail communication with the United States and Canada, and the island is also connected with this country by cable. Churches of all the leading denominations are found nearly everywhere, and in most of the larger towns are well-appointed clubs, libraries, and social organizations of various sorts.

The best months in which to visit Jamaica are November to April inclusive, as these are the coolest and dryest of the year, but one accustomed to the fierce summer heats of our northern cities would find a grateful change in the hills of Jamaica even in midsummer.

Much valuable information concerning Jamaica as a health resort may be obtained from a work on "The Climate of Jamaica," by the Hon. J. C. Phillippo, M.D., published by T. & A. Churchill, London, and from "The Handbook of Jamaica," published annually in London and Kingston. *Thomas Lathrop Stedman.*

JAMBUL. This is the local name applied to the bark and seeds of *Sizygium Jambolanum* De Candolle (*Eugenia Jambolana* Lamarck), a tree belonging to the natural order Myrtaceæ. It is indigenous to tropical Asia and the neighboring islands, where it grows to a large size and bears a crop of edible fruit in July and August. It is also known as rose apple and Java plum. The *Eugenia pimenta*, the common allspice tree, and *Eugenia caryophyllata*, from which cloves are obtained, are both closely allied species. The fruit varies in size from a cherry to a pigeon's egg, and when ripe is olive-shaped, smooth, juicy, and purplish-black in color. It contains a single seed, which is enclosed in a thin, papery shell. All parts of the tree are astringent, and the bark furnishes a beautiful brown dye. The bark is smooth and whitish, and the cell-structure contains a number of characteristic pitted cells which are visible to the naked eye. The chemical constitution of the plant has not received much attention. It probably contains an alkaloid or glucoside, but none has been separated so far. A white crystalline substance has been obtained, termed jamborine, which is tasteless, insoluble in cold water, soluble in alcohol, ether, and chloroform. It is said to possess the active properties of the seeds, but its composition and properties are uncertain. The following analysis of the seeds has been furnished by Elborne: Essential oil, a trace; chlorophyll and fat, 0.27; resin soluble in alcohol and ether, 0.30; gallic acid, 1.65; albumin, 1.25; coloring matter, 2.70; moisture, 10.0; insoluble residue, 83.73.

The plant is highly esteemed in India for its medicinal properties, and is used by the native physicians in the treatment of many diseases. The sap or juice expressed from the leaves and bark contains the astringent properties of the plant, and when mixed with goat's milk is thought to be particularly beneficent in the intestinal disorders of children. The juice, and an infusion of the bark, are also employed in dysentery, diarrhœa, and in leucorrhœa. A liquor, jambava, is prepared from the fruit by fermentation; it possesses a stimulating and tonic action, and is a favorite beverage of the Hindoos. The most important use of jambul is as a remedy for diabetes, and it is in the treatment of this disease that it has acquired notoriety and attracted the attention of the profession during the past few years. It has long been employed for this purpose in the East, where it has the reputation of producing a rapid and, in many instances, a permanent cure. The quantity of sugar and urine is reduced, the many distressing symptoms relieved, and a return of health and strength is said to follow its administration. This treatment was brought to the notice of the English physicians in 1883, by Banatvala, a medical officer in the service of the Madras government, and has been the subject of numerous clinical and experimental researches.

Von Mehring and Graser[1] performed an important series of experiments to demonstrate its power to check the production and lessen excretion of sugar. They produced artificial diabetes in animals by the administration of phloridzin, and carefully estimated the amount of sugar excreted when phloridzin was given alone, and when it was given in combination with jambul. The diminution was found to be invariable and very decided. The following figures indicate the results in three experiments:

Sugar excreted without jambul	12.2	10	10
Sugar excreted with jambul	2.1	1	1.5

They also proved that it was devoid of any toxic action, as very large quantities were given without producing any ill effects.

Experiments have also been made to show its inhibitory action on saccharine fermentation by adding it to a solution of starch and malt, and it has been clearly shown that the quantity of sugar is reduced in accordance with the amount of jambul present. In one instance it was found

that a solution of rice starch with a definite proportion of malt produced 27.4 parts of sugar; when fifteen grains of jambul were added the amount was reduced to 9.4 parts, and when twenty-five grains were used there was only 1.3 part of sugar formed.

Accompanying this evidence in favor of the drug have been a number of reports of cases treated, and in nearly all it was found that the desired effect was produced in a greater or less degree. Among these are reports by such observers as Kingsbury,[2] Saundly,[3] E. H. Fenwick,[4] Mahomed,[5] Egasse,[6] Villy,[7] Lewaschew,[8] Lawrence,[9] and Britto.[10] In some of the cases in which it was used it failed altogether, in others the sugar reappeared immediately the remedy was discontinued, and frequently it would only lessen the symptoms in a slight degree; but the general tenor of the reports is in favor of the remedy. Villy, who views this treatment more sceptically than any of the others, acknowledges that it is of service "in cases of moderate severity, provided the diet be absolutely restricted."

In reviewing these reports, there is apparent a great deal of uncertainty in the employment of the drug. Some of the cases were treated with small doses and the most satisfactory results were obtained; in other instances the reporters state that in larger quantities only can any benefit be expected. The same variation is observed in the dieting of the patients: some were allowed to eat freely of any food they desired, while others were restricted to a proper diabetic regimen, and in both classes were successes and failures recorded. A more scientific turn has been given to the study of the remedy by the British Medical Association, in empowering its therapeutic committee to inquire into the mode of action. A supply of the fresh seeds was obtained and furnished, with certain directions, to such of its members as desired to make use of them.

How the drug acts, or what are the forms of the disease in which it is indicated, have not been determined. It has been thought to act by simply checking the transformation of starch into sugar, producing the same effect as a carefully prepared diet; but the experiments of Graser would indicate its action to be of a more radical character, and in many of the cases in which its use has been followed by marked benefit, a restricted diet and numerous other remedies had previously been employed. Villy, who studied the drug under the direction of Dujardin-Beaumetz, considers that any beneficial action only accompanies the use of the remedy when starchy food is excluded, and he seems to think that it has very little power in preventing the transformation of starch into sugar. He repeated the experiments with solutions of starch and malt, and found that instead of the diastatic ferment being checked, the conversion of the starch proceeded more rapidly with the jambul added than without its presence.

The seeds and the bark both possess the anti-diabetic action, but the seeds are the more active of the two. A paper presented by Dr. T. Stevenson, of Bombay, to the Pharmaceutical Conference, held at Edinburgh, 1892, states that the fresh seeds, or an extract prepared from the fresh seeds, is the most serviceable and the only certain method of securing the medicinal properties. Under any circumstances, it is recommended that the seeds should be carefully preserved and only reduced to powder as required. Some such variation in the active properties of the drug may account for the uncertainty of its action and the difference in the quantity administered. The usually recommended dose is five to ten grains of the powder, or five to ten minims of the extract, three or four times a day. This, however, appears to be inadequate, and much larger doses are now advised. Dr. Britto, who reports from India his successful treatment of a number of cases, gave it in doses of one drachm of the powder, or one fluid drachm of the extract, three times a day; and Professor Lewaschew, who reports his experience of two years, in which he employed the drug with marked success, advocates it in doses of as much as from twenty to forty grammes (5 to 10 drachms) in the twenty-four hours. The British Association, in their recommendations for its experimental use, state that the dose of the powdered seeds should be from one drachm to one ounce daily. No toxic action follows its use, but instances of nausea and depression have been reported from its continued use.

JOINTS, DISEASES OF THE. TREATMENT IN GENERAL.—*Local applications* of all kinds, poulticing, blistering, the cautery, and ice-bags, so much used a few years ago, are no longer employed with the expectation that any effect will be gained upon the disease itself, or that anything more than temporary relief to the superficial symptoms will be attained. The same may be said of compression in tubercular synovitis. Massage and passive motion are not only of no use, but are productive of much harm when used during the course of the disease. After the disease has terminated, they have a certain cosmetic value; they hasten the time when the fullest possible motion and the greatest attainable plumpness are regained, but they accomplish nothing which will not be sooner or later gained by use alone.

Subcutaneous Injections.—Various medicaments have been injected into masses of tubercular tissue and tubercular abscesses, but none have held the confidence of the profession except iodoform in glycerine or olive oil. This is used in ten per cent. strength and carefully sterilized. When injected into tubercular tissue a few drops are deposited here and a few drops there throughout the mass. When used in abscesses, the abscess contents are as completely evacuated as possible, and then from one to four drachms are injected, and moderate compression applied. The cavity usually refills, and the process may have to be repeated many times; or after any one of the injections it may not refill, but gradually close, and the tubercular lining membrane shrink away. If the injection be kept strictly aseptic a cure is effected in much less time than could be had in any other way; but if septic infection does result, the injection proves an injury instead of a benefit. In young children who fear the pain of the injection, the advisability of the procedure may be questioned, it being borne in mind that treatment by brace must in any case be continued for many months.

Fixation and Traction.—The treatment of chronic joint disease by "motion without friction," attained by elastic traction in an ambulatory apparatus, is no longer attempted. All surgeons now agree upon the necessity of fixation during the active stage of the disease. At a somewhat later time many allow motion within the limits of muscular restriction, while others insist upon immobilization until a complete cure appears to have been accomplished.

Traction, or "distraction," is employed either for the fixation which it gives (Judson); or because of the increased area of motion possible during its use (Sayre); or as a means for allaying muscular spasm (Shaffer).

It is obvious that whatever will most quickly allay muscular spasm is of prime importance. The advocates of traction believe that traction is of the first importance, and the best, if not the only, means for satisfactorily doing this. On the other hand, the advocates of pure fixation claim that fixation alone without traction will more quickly allay the spasm than will traction, or fixation combined with traction. The two methods have not been given a fair, unprejudiced trial and comparison. Meantime, the majority of the profession use a more or less perfect, and more or less defective, combination of both principles.

In treating joint diseases in the lower limbs, traction during recumbency and during walking are quite differ-

ent problems, and we feel quite convinced that continuous, uninterrupted traction cannot be had by any splint upon which the patient walks.

HIP DISEASE.—The etiology of the various deformities of hip disease has recently been studied by Dr. A. M. Phelps, of New York, who arrived at the following conclusions:

Abduction always precedes flexion, or is attended by it, in the first stage.

Abduction and outward rotation are always present in the second stage. Flexion is nearly always present, but is absent in a few cases.

When the limb is flexed beyond forty degrees, and frequently at a much lesser degree (twenty degrees), it quite rapidly passes to the deformity of adduction, inward rotation, and flexion, whether the capsule contains fluid or not.

Assuming the work of the glutæus maximus operating in a given triangle with two pounds and a half weight to be fifty pounds, other muscles operating in different triangles of different weights can be accurately estimated as to their comparative strength. Following this rule, it was found that the glutæi muscles were capable of one hundred and thirty-one pounds, whereas the adductors were only capable of one hundred and sixteen pounds, proving that the abductor group was much stronger than the adductor in the subject examined. From clinical observation it was concluded that the reason why the limb went over to the deformity of the third stage of hip-joint disease, was because the actions of these muscles were all changed by the flexion of the limb, or from pathological destruction of the joint changing or annulling the action of the muscles by destroying the leverage.

In the first stage the limb is slightly flexed and abducted to relieve the tension of the capsule. This deformity is increased as the case passes to the second stage by the spasm of the muscles about the hip-joint. The great glutæi, outward rotators, tensor vaginæ femoris, and flexors have the advantage of leverage. As a rule, the deformity of the third stage appears only after flexion to twenty-five degrees has taken place. This is because after the limb has passed to twenty-five degrees of flexion, the adductors to a very great extent become internal rotators; the external rotators almost totally lose their power as external rotators, and become abductors (with the exception of the quadratus femoris and obturator externus), and the tensor vaginæ femoris becomes a powerful inward rotator.

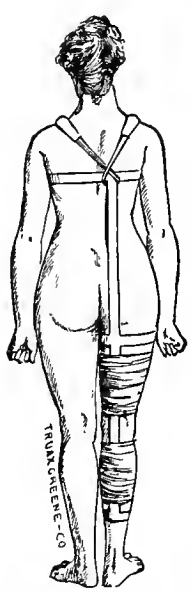

FIG. 368.—The Thomas Hip-splint Applied.

Erratic deformities occur from partial or complete dislocations, and from shortening of the neck of the femur, which destroys the action of the flexors, and often of the adductors, by changing the leverage. Extreme flexion may be accompanied with abduction and outward rotation; or adduction may be accompanied with outward rotation.

The treatment may be by fixation with a plaster-of-Paris splint, or by a brace. If the plaster splint be made use of, it should extend from the ankle to the axilla. It is difficult to apply without favoring increased flexion deformity. Bartow, of Buffalo, partially suspends patients in the conventional suspension apparatus and applies the splint, while the patient bears a part of his weight by the well limb upon a block, the affected limb dangling, or gently pulled downward into the best possible position.

The Thomas hip-splint (Fig. 368) is the only purely fixative splint in general use. The objections which have been raised to it are: (1) That it does not furnish complete fixation; (2) that it does not prevent subluxation; (3) that it does not counteract muscular contraction; (4) that it increases pain because of its leverage action. It is proper to say that these objections are raised by surgeons who have not used a properly constructed splint upon the principles laid down by Mr. Thomas, and the objections are therefore purely theoretical, and based upon an imperfect knowledge.

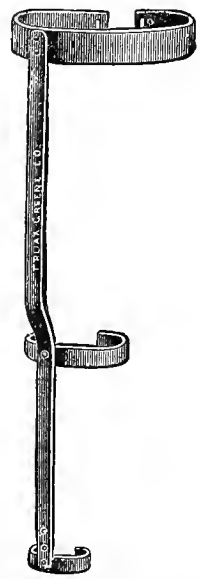

FIG. 369.—The Thomas Hip-splint, as used by the Author.

The persistent deformity of hip disease is flexion. So long as flexion is present, and so long as muscular spasm tending to flexion is present, the splint, by its direct antero-posterior leverage action, if properly applied, absolutely controls antero-posterior motion. Lateral motion, to which there is less tendency, is controlled in the same way, but less efficiently. When there is no longer any deformity, and when the joint has so far recovered that muscular spasm no longer tends to deformity, the fixative power of the splint is greatly lessened; but at that time a certain amount of motion does no harm, as is admitted by those who object to the use of this splint. As to subluxation of the femur during the use of the splint: One such case has been reported, but there is no evidence to show that the reporter of the case knew how properly to use the splint. On the other hand, subluxation now and then happens when the traction-splint is being used, both in walking and recumbent cases. As to muscular spasm: Whatever is able to keep the parts in most perfect quiet, that most quickly relieves the spasm. In my experience the Thomas splint does this; and after using the long traction hip-splint in many hundreds of cases, I have entirely abandoned its use. I am very certain that pulling upon the muscle is not logically, nor is it clinically, the most successful way to abolish the involuntary muscular spasm of joint disease. That which acts to allay the inflammation from which the spasm arises ought to most quickly allay the spasm, and in practice we find that immobilization of the joint does this. As to the increase of pain: It does in many cases increase the pain for the few days during which the deformity is being overcome, but the sum total of pain had better be condensed into two or three days than spread over the days and nights of two or three months. That injury is inflicted by the leverage action which causes the increase of pain has not been proven by any increase in the number of patients having abscesses, stiff joints, or short legs.

The Thomas hip-splint (Fig. 369) consists of a main stem and several bands. The stem is of flat bar iron, from $\frac{3}{16} \times \frac{3}{4}$ to $\frac{1}{4} \times 1\frac{1}{4}$ inch; in length, reaching from the lower angle of the scapula to the lower third of the leg. The size of the bar must be large enough to prevent any bending or tremor. The chest band is of the same width as the main stem, but thin enough to be bent by the hands of the surgeon in fitting it to the chest. In each end is forged a hole three-fourths of an inch in diameter, and at its middle it is riveted to the top of the main stem. It is long enough to surround the chest below the axillæ. The thigh and calf bands are of somewhat lighter iron; the thigh band is riveted to the stem at such a point that it shall be a little below the perineum; and the calf band is at the lower end of the splint. Both are large enough to nearly surround the limb at the points indicated. At times an abduction or an adduction wing is attached to the main stem at a point where it will pass around the flank of the patient above the iliac crest and below the ribs. It is of iron of the same thickness as the chest band.

In the main stem are two bends dividing it into a

straight body portion and a straight leg portion, the lower portion being parallel to and slightly in advance of the upper portion. The lower bend is opposite the glutæo-femoral crease, and the upper one opposite the hip-joint. The splint is applied by opening out the wings of the bands on one side and slipping it under the patient until the stem rests in proper place, when the wings are again bent in to the side of chest and leg. The splint is supported by a strip of broad bandage looped around the main stem beneath the chest band, and carried over each shoulder and down to the holes in the ends of the chest band in front, after the manner of suspenders. The limb is bandaged to the splint by an ordinary roller from the bottom to the thigh band, or by a short piece at the bottom and another above the knee, or by a figure-of-eight around the knee.

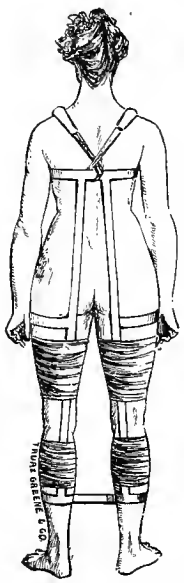

FIG. 370. — The Double Thomas Hip-splint.

If the limb cannot be brought fairly down, the brace may be bent at a point opposite the hip-joint and straightened during the succeeding three or four days; but this should not be done if it can be avoided. If the splint tends to shift to right or left, the wings on the side toward which it moves should be somewhat opened and those on the opposite side drawn closer in to the patient. Abduction and adduction are corrected and prevented by an extra wing attached to the main stem at such a point that it will pass around the flank on the side toward which it is desired to draw the limb. When rapidly straightening a deformity, and in cases where the muscular spasm is intense, the skin underneath the brace should be changed once or twice a day and kept dry and well powdered. In moving a patient with a very sensitive joint, the patient places his well limb across the affected member, while the assistant lifts him by placing one hand under the brace and limb at the back of the knee, and with the other grasps the chest band.

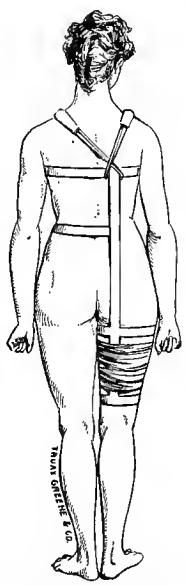

FIG. 371. — The Thomas Hip-splint, shortened for walking during convalescence.

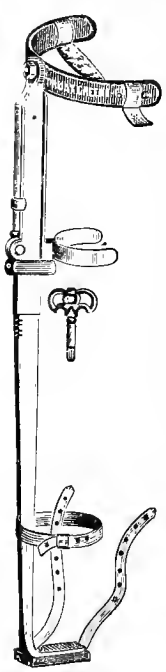

FIG. 372. Judson's Hip-splint.

Judson's splint (Fig. 372) is the most rigid of the long traction hip-splints. The hip band is of heavy steel coated with hard rubber. This is firmly bolted to the head-piece of the side-bar, so that there may be no motion between them. The side-bar and sheath are of steel, about one-quarter of an inch thick, and in width from one-half inch at the bottom to one and a quarter inch at the upper part, where most of the strain must be borne. Adhesive plasters attached to the thigh and leg give means for traction, and a perineal strap gives counter-traction as in the conventional traction hip-splint.

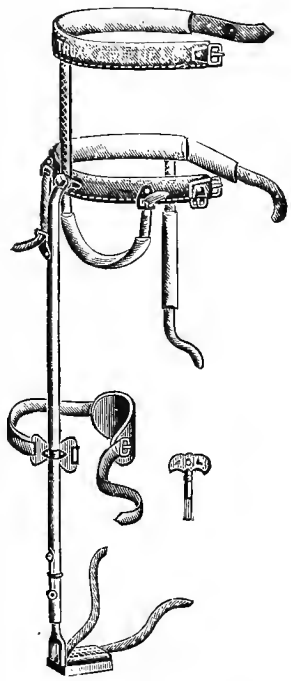

FIG. 373. Ridlon's Traction Hip-splint.

Ridlon's hip-splint (Fig. 373) (no longer used by the author) consists of one of the earlier forms of the Taylor hip-splint to which has been added a side-bar extending up the side of the body to the axilla, and a chest-band surrounding the chest at this point. A strong bolt fastens the chest-piece, the hip-band, and the extension-bar immovably together. Traction and counter-traction are made in the usual way. The advantage of the splint over the usual forms of traction splint is, that the patient cannot voluntarily bend to any extent from foot to axillæ.

Phelps's splint (Figs. 374 and 375) is a combination of the ring of the Thomas knee-splint, the usual extension-bar placed, however, at the inner side of the leg and thereby subjected to less lateral strain, and Ridlon's chest-piece. To these is added a lever to exert lateral traction by pulling outward upon a band passed around the thigh. The splint more rigidly immobilizes than does Ridlon's splint, but has this disadvantage, that it cannot be applied while any considerable deformity is present. The deformity must first be reduced by other means.

Correction of Deformities.— Flexion, abduction, and adduction, when disease is still present, should be corrected as rapidly as possible by leverage action, supplemented or not by traction, as the case may demand. True shortening cannot be remedied, but may be obscured by placing the limb in abduction and slanting the pelvis. Deformities present in cured cases may, if there be any motion present, be corrected by leverage, supplemented or not by section of the shortened soft parts. If there is no motion and no muscular spasm, section of the bone by saw, or preferably by chisel, is indicated, supplemented or not with section of the shortened soft parts. Whatever method is employed to correct the deformity, the limb must be thoroughly immobilized until all pain, tenderness, and muscular spasm have subsided.

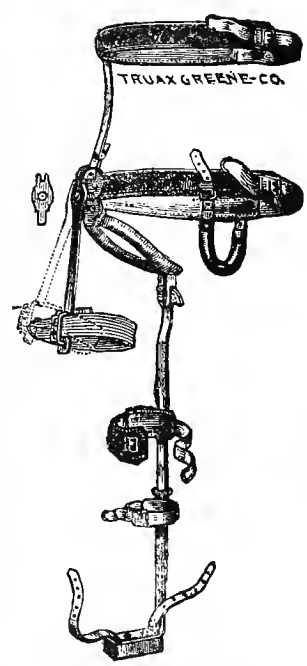

FIG. 374.—Phelps' Hip-splint.

KNEE-JOINT DISEASE.— The same principles govern the treatment of disease at this articulation as at the hip, and need not be rehearsed.

The most effective apparatus is the Thomas knee-splint (Figs. 376 and 377). It is made in two forms: the bed splint and the caliper splint. They differ only in

the manner of termination at the bottom, as will be seen in the description. The splint consists of a thigh-ring and two side-bars; it is made of one-fourth to seven-sixteenths inch iron wire, the ring being welded to the side-bars and sloped from without inward and from before backward. The angle formed by the lateral plane of the ring and the inner bar is about 135 degrees; the posterior angle formed by the plane of the ring and the inner bar is from 55 to 70 degrees, depending upon the thickness of the padding of the ring. The slope of the ring must be sufficient to leave that part of the ring which comes beneath the tuberosity of the ischium a little lower than any other part. The shape of the ring is irregularly ovoid, considerably flattened in the front and drawn out at the inner portion of the back. The shape varies somewhat, depending upon the thickness of padding to be put on.

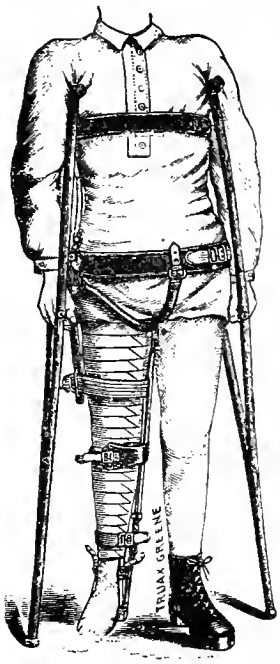

FIG. 375. Phelps's Hip-splint Applied.

The ring is padded firmly with felt and covered with tan sheep-skin put on wet, stretched snugly, and sewed on the outer surface of the ring. When the brace is to be used in bed it is made to extend six or eight inches beyond the foot, and usually is dimpled at the extremity so that the straps from the adhesive plasters will not slip, if they are used to give fixative traction. When it is desired to transform the bed-splint into the caliper, the portion extending beyond the foot is cut off an inch below the sole and an inch of each end bent to a right angle toward the opposite bar. These bent ends are sprung into a hole or tube set transversely through the heel of the shoe. In either splint a sling of leather, from four to six inches wide, is stretched across from one bar to the other at the back of the knee, and another narrower piece at the back of the ankle. A pad is placed over the front of the thigh, close down to the patella, and another over the shin just below the knee-joint, and backward pressure is made by strap or a piece of bandage passed across the pad, beneath each side-bar and back across the pad and fastened. When any backward displacement of the tibia is present, the sling at the back is slipped lower and only the thigh-pad used for backward pressure. In using the caliper splint care must be taken that it shall be long enough to keep the heel clear from the sole of the shoe in walking. The form of Thomas knee-splint extending four inches below the foot and terminating in a patten bottom is no longer used, as it does not give efficient immobilization.

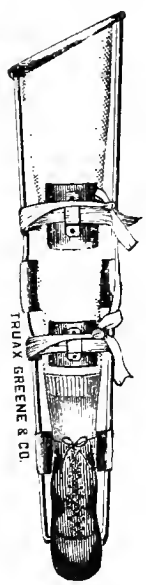

FIG. 376. — The Thomas "Caliper" Knee-splint, for walking.

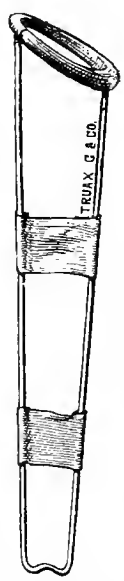

FIG. 377. — The Thomas Knee-splint for use when patient is in bed.

ELBOW-JOINT DISEASE.—This joint can be most effectively immobilized in a very simple manner. A strip of broad bandage is tied about the wrist, the forearm is flexed to such a point as will be most useful in case anchylosis results, the bandage is then carried to the neck and tied, and then around the neck and again tied, so that neither hand nor head can be drawn from their respective loops.

At first sight it would seem that this sort of immobilization would be far from complete, but the contrary is the case. The position which the forearm assumes in relation to the arm in elbow-joint disease is one of extension to about one hundred and sixty degrees, so that if the forearm be held flexed to about seventy-five degrees, the tendency to extension acting in opposition to the restraining influence of the sling gives effective immobilization. The patient does not voluntarily flex the forearm beyond the position of restraint so long as the disease is sufficient to be aggravated by such motion.

In diseases of the other joints nothing worthy of record has been recently advanced. *John Ridlon.*

JOINTS, MOVABLE BODIES IN. There is little, indeed, of unusual moment that can be added now to that which has already been stated in the original article written for the HANDBOOK in 1886. Now, as then, joint derangements are due, not only to the effects of injury and disease on the component parts of the articulation, but also to the presence in them of the products of various histological processes that happen elsewhere in the body, in similar tissues. The semi-lunar cartilages are common seats of injury and disease in the knee, as not only themselves, but also the ligaments connected with them, suffer conjointly and separately, or with interchangeable relationship with each other. The injuries and diseases characteristic of these joint-structures constitute the most important items of affliction incident to the life-history of joints thus provided. The cartilages themselves may be displaced, bruised, crushed, or torn, and the ligaments maintaining them in proper relationship with the articular surfaces and properly attuning their functional movements, may be stretched, bruised, or ruptured. The internal semi-lunar cartilage of the knee-joint and its attachments suffer more frequently than do the external similar structures. The exact reasons for this are somewhat problematical. It may be accounted for by the fact of the greater degree of functional activity that is present during motion at this portion of the joint; for the internal semi-lunar cartilage moves over a greater area of articular surface than the other, in order to meet its functional requirement in connection with the inner condyle of the femur, which condyle passes through the segment of a larger circle than its fellow. Also greater weight is received on the inner condyle than on the outer, and, too, it is more exposed to external violence than is the former. Functional derangement of these cartilages, resulting in their becoming pinched between the moving articular surfaces, is predisposed by any roughening process that hinders the harmony of action necessary for the proper performance of the advancing and retiring movements imposed on them during activity of the articular surfaces between which they are placed. And should this condition be present together with relaxed ligamentous attachments of the cartilages, then, indeed, will the danger of pinching be increased, and even actual displacement be threatened. Especially is this true of the inner cartilage in the presence of an actual extension with supination of the leg. In their normal state these cartilages cannot be broken, although they may be bruised, torn, and twisted. If, however, they have become hardened by morbid processes, then it is not impossible that they may be displaced or broken by severe circumscribed violence directed from without. They may be broken, or their coronary attachments may be ruptured under these circumstances by violence, while the weight

of the body is borne on the extended limb, but they cannot then be displaced. Violence directed against the outer border during the act of flexion of the leg and thigh, may cause them to be torn from their attachments and even ruptured, and then if extension follow quickly and forcibly, they may be overridden by the opposing articular surfaces, and thus held or be forced to the posterior part of the joint cavity. If the joint be already impaired by ligamentous relaxation and other structural changes, then, surely, derangement and displacement of these so-called cartilaginous structures much more readily takes place.

The special indications of semi-lunar involvement relate more especially to modifications of the normal contour of the joint surface at the site of the cartilages, as determined by palpation. With the leg extended, the external rounded borders of these cartilages can be easily felt in the normal state, and it will be noticed that they will recede gradually from the touch as the limb is being flexed, causing instead a marked depression corresponding to their former site. If the cartilage be displaced outward, then undue prominence is noted at that point, which may or may not disappear with flexion of the limb. The semi-lunar cartilages may become displaced outward at other aspects of the joint, but in these instances their mobility is less influenced by the normal movements of the joint than in the first instance. If the displacement be inward toward the centre of the joint, then the degree of extension which may be attainable need not return the cartilage to its normal site, and, therefore, a depression is noted in lieu of the normal contour of the cartilage. If the coronary ligaments be ruptured, these cartilages will recede and advance perceptibly during flexion and extension of the leg, provided the articular surfaces, and those of the adjacent cartilage, are smooth, and properly lubricated, If otherwise, they may be easily pinched and perhaps overridden during extension of the limb. One should judge of the nature and extent of the injury of a joint by carefully comparing its physical and functional characteristics with those of its uninjured fellow.

Treatment.—If the cartilage be displaced, its prompt reduction should be attempted. Various methods of procedure are advised to accomplish this purpose. The chief element of a successful reduction is based on the fact that flexion of the leg relaxes the connecting structures of the joint in direct proportion to the degree of that act. Now, since relaxation loosens joint tension, it follows naturally that loosening of the tension favors the restoration of the displaced cartilage, either by its own inherent elasticity or by direct manipulation, in the best possible manner. For this reason various degrees of extent and rapidity of flexion, combined with supination and pronation of the leg, are advised, for the purpose of reduction. The following, advised by Allingham, is sufficiently comprehensive to suggest, and probably even meets the demands incident to, displacement. "Flex the leg as much as possible on the thigh, drawing upon the tibia as if to separate the articular surfaces from the femur. Then rotate the tibia inward, if the internal cartilage be displaced, and outward, if the external cartilage be displaced. Both movements should be resorted to if the usual one does not succeed. Then extend the leg on the thigh quickly, but not with great violence, at the same time pressing with the thumb upon the projecting cartilage." After reduction, rest and immobility, until the danger of inflammation has subsided, will commonly suffice. If reduction fail of accomplishment, then one of two plans can be pursued :—

1. The employment of massage and passive motion, after the symptoms incident to the injury have subsided. This course will in time restore the function of the joint, although at intervals derangements will ensue, the same as may happen even when the reduction is accomplished at first.

2. The exploration of the joint through a liberal perpendicular or oblique incision made into it at the aspect of the displaced structure, about three-fourths of an inch from the ligamentum patellæ. If the integrity of the cartilage will permit, it should be returned to its proper position, and be stitched there with fine aseptic silk. If this be not allowable, on account of the great extent to which its structure has been damaged, it should be removed entirely. In either instance, finally, the joint should be irrigated with an antiseptic solution and closed by two rows of sutures—the first including only the synovial membrane and its closely adjacent connective tissues; the second, the remaining tissues of the wound. Either silk or catgut can be used, as best suits the wish of the operator. The employment of drainage will depend greatly on the extent of handling to which the structures of the joint-cavity have been subjected. Ordinarily it need not be employed; still, the introduction into the joint of carbolized horse-hair, or a small rubber tube, for drainage purposes, cannot in itself do harm, and should, therefore, be employed when, in the judgment of the operator, such a step is indicated.

The alar structures of a joint may become so elongated or enlarged, as the result of disease, as to be pinched by the articular surfaces. Extravasations of blood within their folds may so change their relations with the joint surfaces as to cause pinching at once, or bring it on at some later date, on account of the formation of fibrinous bodies within them, which remain attached to the borders of these structures, or are eventually disconnected and wander freely in the cavity. Histological changes taking place singly or otherwise in the various tissues constituting a joint, often lead to the presence within it of movable and attached bodies that can be characterized according to the nature of the process causing them, or the structure of the tissues that give them birth. Consequently, they may be described as of fibrinous, fibrous, cartilaginous, fibro-cartilaginous, osteo-cartilaginous, tuberculous, and biform origin, etc. The symptoms of the presence of these morbid bodies are illustrative of joint derangement in the full sense of the term, as compared with those of cartilaginous displacement proper, and little of practical importance can be added now to what has already been stated elsewhere in the Handbook on this subject.

Dr. Robert F. Weir recently called attention (*Medical Record*, July 16, 1892) to an interesting condition causing joint derangement of the knee, which simulated in all essential respects the presence in this joint of a movable body. Exploration of the joint revealed the fact that a duplication of fibrous membrane extended from the under surface of the patella and the adjoining surface of the femur to such a length as to be caught between the articular surfaces during flexion, thus "locking" the joint, and also impeding extension. A grating sound beneath the patella attended the establishment of motion in the two cases of this disease which he had observed. Both were readily cured by removal of this obstructing agent. The treatment for movable bodies relates to the manipulations employed to overcome the joint-locking incident to them, which differs in no essential respect from that used to restore displaced semi-lunar cartilages. Vigorous extension of the leg, during its complete flexion, with or without rotation, will commonly dislodge the troublesome agent and relegate it, for a time at least, to some remote recess of the joint cavity.

The *operative treatment* is the most important, since it offers the only means of prompt and permanent relief, and also because it is attended with an element of risk to the patient which begets at the same time a respectful consideration of the joint cavity on the part of all those responsible for the result of operative measures. The following statement presented by Tuttle will emphasize the operative measure and its dangers much more pointedly than mere words alone can do. It is very important, in-

	Cases.	Cured.	Failures.	Mortality.
		Per cent.	Per cent.	Per cent.
Beamdorf	216	66.2	18.99	14.81
Lorry, 1860	167	68.86	19.76	11.38

Tuttle	107	97.19	2.81	.....

deed, to note the difference in the results as modified by the recent antiseptic measures, since the results in no uncertain manner impress upon one the fact that the wise use of modern methods relieves nearly all of the afflicted, without causing any of them the loss of life or limb.

Joseph D. Bryant.

KAVA-KAVA. This is the native name of *Piper Methysticum*, a shrub belonging to the natural order Piperaceæ. It is indigenous to the Polynesian Islands. It has acquired a local reputation as a remedy for dropsy and painful affections of the bladder and the urinary tract, but it is chiefly prized as the source of a native national beverage. The plant is reduced to a pulpy mass by mastication and allowed to ferment, until an intoxicating liquor is produced. The primary effect is as a stimulant, but ultimately it causes a peculiar form of intoxication in which the limbs and body are uncontrollable and helpless, while the mental faculties are clear or slightly dazed. The root is the part employed for medicinal purposes, and has been closely investigated by Dr. L. Lewin, of Berlin, who directed attention to its importance as a remedial agent. He analyzed it and obtained an essential oil; two resins, alpha- and beta-resin kava; and a neutral crystalline principle called *kavahin*, or *methysticin*, which is closely allied to *piperine*. The crystalline body exists to the extent of one per cent., but has been found inactive. The alpha-resin, which is obtained by means of alcohol, and is insoluble in water, contains the medicinal properties of the plant, and is thought by Lewin to be the active ingredient. It has, however, been shown that the watery infusion also is useful, and this would indicate that the virtues of the plant are not limited to the resin itself. At present the resin and the fluid extract, not miscible with water, are the preparations employed for medicinal purposes. Kava-Kava has formed the subject of an exhaustive study by Dr. Cerna (*Therapeutic Gazette*, January, 1891) who arrives at the following conclusions regarding its physiological action: Moderate doses produce a stimulating effect, particularly on the central nervous ganglia; in larger quantities it produces general anæsthesia, and diminishes and ultimately abolishes reflex action by influencing the spinal cord, and probably also the spinal centres. The great muscular weakness observed is not due to any action on the higher cerebral centres, as they maintain their normal functional activity. Very large quantities depress the circulatory and respiratory systems, and, in poisonous doses, death is produced by failure of the respiration, or by cardiac paralysis. Placed on the tongue, it at first causes a burning sensation, which is followed by numbness and anæsthesia, which continue for some time and are accompanied by a free flow of saliva. On the cornea and conjunctiva the same effect is produced. The local anæsthetic action is said to be equal to that of cocaine, but its use is restricted by the insolubility of the preparations in water.

Kava-Kava is advocated as a remedy in cystitis, gonorrhœa, and chronic inflammatory conditions of the mucous membrane of the urinary organs. It also possesses a diuretic action, and has been used with success in dropsy. Its tonic and stimulating properties add to the general well-being of the patient, and increase its beneficial action. Its administration should be accompanied by copious draughts of water, which soon promotes a plentiful flow of urine which rapidly moderates the inflammatory action and exerts a remarkably soothing influence. This is followed by a lessening of the purulent and catarrhal discharges. The fluid extract is the most convenient preparation to use, and has been employed with decided success. It may be given in doses of twenty to sixty minims three times a day, and has been combined with sweet spirits of nitre and glycerine when these are indicated. The alpha-resin is given in doses of one to one and a half grain, three times a day. A solid extract is prepared, the dose of which is two to six grains. The principle, kavahin, is not employed, as its therapeutic action and dose are uncertain. *Beaumont Small.*

KILRUSH AND KILKEE. Popular sea-side resorts in County Clare, Ireland. There are a number of ferruginous springs near these places. Kilrush is on the north shore of the estuary of the Shannon, and Kilkee faces the Atlantic Ocean. At the latter place there is a fine sandy beach. The climate of these resorts is on the whole good. It is decidedly bracing, and at times the westerly gales are trying. The amount of rainfall is not greater than the average for Great Britain. The accommodations are rather primitive. There are many opportunities for excursions on land and sea. Scattery Island is only one mile from Kilrush. *Edmund C. Wendt.*

KISSINGEN. The principal features of this important German spa have already been described in Vol. IV. of this Handbook. The writer has had occasion, on his several visits to the place, to gather abundant evidence as to the good results obtained there in suitable cases. It is, however, one of those resorts where it is by no means superfluous to remain under strict medical supervision while taking a course of the waters. Patients acting without professional advice are at times injured by the waters.

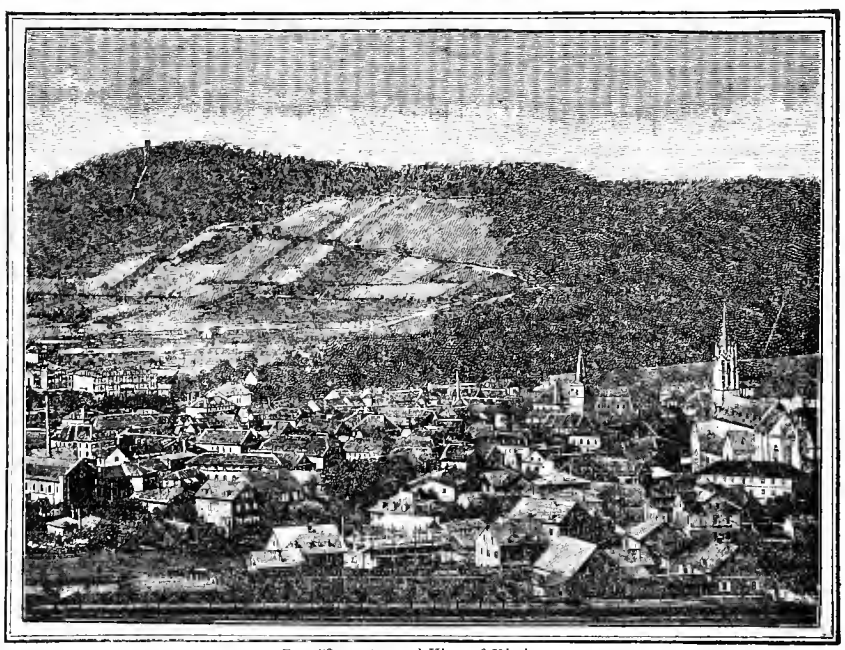

Fig. 378.—General View of Kissingen.

Recently some needed sanitary reforms have been completed at Kissingen. The little town is now well drained and is supplied with good drinking water. It is so pleasant a place to spend a summer in, that many visitors now go there who are not invalids.

Kissingen has excellent facilities for all kinds of baths, inhalations, mechanico-therapeutics, massage, etc. There are also various private medical establishments, under supervision of competent physicians. Dr. v. Sohlern has a special sanitarium for the treatment of gastric disorders, and the results of treatment there are known to be often highly satisfactory.

In regard to the brine baths, Dr. Thomas More Madden, after a recent inspection (*The Provincial Medical Journal*, December 1, 1892), speaks as follows:

"About a mile from the other springs, to the north of the town, rises the Soolensprudel. This well is contained within a handsome square building facing the river. The hall occupies the entire central part of the structure, and is lighted from the dome, while at each side different galleries run round. In the middle of this apartment is a raised structure, somewhat like an immense beehive, with glazed cover, about two feet high, beneath which is the Soolensprudel. The shaft of the well, seen through this cover, is about twenty feet deep by about eight feet in diameter, and seems to be lined with woodwork. Through the bottom of that shaft an artesian well was bored in 1823 to the depth of nearly three hundred feet in the sandstone, and this it is which now supplies the Soolensprudel.

"This source presents a very remarkable phenomenon, namely, it intermits, or ebbs and flows, with great regularity, eight or nine times daily. If we arrive a little before the 'flow,' on looking down the shaft through the thick glass cap we see the well apparently empty of water; we then hear a distant rumbling noise, which gradually becomes louder, and draws nearer, till in about half an hour from the time it was first heard, the water is seen foaming below; it gradually ascends, and in another quarter of an hour reaches within a few inches of the top of the well, covered with white foam, and hissing and seething with great turbulence. Above the water hangs a heavy layer of carbonic acid gas, rising and falling with it. This gas is collected and ingeniously utilized in various forms of gas baths. Indeed, the entire system of vapor, gas, and water baths in the establishment is extremely perfect.

"Internally used this water is strongly purgative, and diluted, as from its strength it could not otherwise be drank, it is employed in the same class of cases as the other springs. It is, however, principally used for bathing, in rheumatic, neuralgic, and cutaneous affections. It acts as a powerful stimulant to the skin, producing redness and considerable irritation of the surface. From its close resemblance to sea water, having, however, in addition, a small proportion of iron and a considerable amount of carbonic acid gas, it might, and perhaps even more advantageously than sea-water, be employed in scrofulous cases. The mother lye, or concentrated saline water of the Soolensprudel, is applied with wonderful results as a local application to scrofulous glandular swellings and similar affections."

Physicians and their families are very courteously treated at this spa, and annually visit Kissingen in large numbers. The hotels are large, and many of them are quite modern in the provision of comforts.

Edmund C. Wendt.

KNOCK-KNEE. In the treatment of knock-knee by mechanical means two essential points must be insisted upon during the period of attempted correction of the deformity, namely, the patient must be kept off his feet, and the mechanical device must be applied with the knee in full extension, and be capable of constantly maintaining that position without motion at the joint. The discredit which has generally fallen upon the mechanical treatment of this deformity, and led to the employment of operative procedures, is due to the use of braces so constructed with a joint at the knee as to allow the patient to walk with a reasonable degree of comfort. Only when the knee is fully extended is the leverage action of any brace effective; as soon as the leg begins to flex, the deformity becomes less, and, before flexion reaches a right angle, entirely disappears, and the feet can be brought together. This is due to the fact that the divergence from the normal relations of the condyles is more a longitudinal than an antero-posterior one. The divergence of the condyles from the normal may be either a shortening of the external, or an elongation of the internal; upon this relation depends the choice between the operations of Ogston and MacEwen in operative cases. If the internal condyle is considerably elongated and the external condyle of normal length, obviously Ogston's operation, which allows the split-off inner condyle to slip upward, is to be preferred to MacEwen's, which practically elongates the outer condyle without shortening the inner, by the gap at the outer side of the lower end of the divided femoral shaft. This deviation of the condyles from the normal should also be taken into consideration in choosing between the operative and the mechanical treatment; otherwise it may be found, when the deformity has been corrected, that one lower extremity is considerably longer than the other, as in Fig. 379, and that the deformity resulting from the treatment is quite as serious as that for which the treatment has been employed. Unlike bow-legs, when the choice between mechanical and operative treatment depends upon the age of the patient and the rigidity of the bones, the choice in knock-knee depends upon the nature and location of the abnormality. In all cases the knock-knee can be corrected by a brace; nevertheless, Ogston's operation is to be preferred if the deformity consists solely of great elongation at the internal condyle, and MacEwen's in those older cases where the shortening at the outer

Fig. 379.—Elongation of Left Limb due to Correction of Knock-knee by a Brace.

condyle equals or exceeds the lengthening at the inner. A description of these operations will be found under their separate headings. The mechanical treatment consists of the application of some rigid splint, a simple form of which is represented in Fig. 380. It consists of a piece of flat bar-iron placed along the outer side of the limb, reaching from the greater trochanter to the sole, forged round at the bottom, bent at a right angle, and passed into a tube or hole in the heel of the shoe; attached to this, at a point just above the malleolus, is a padded band of thin iron reaching two-thirds around the ankle; at the

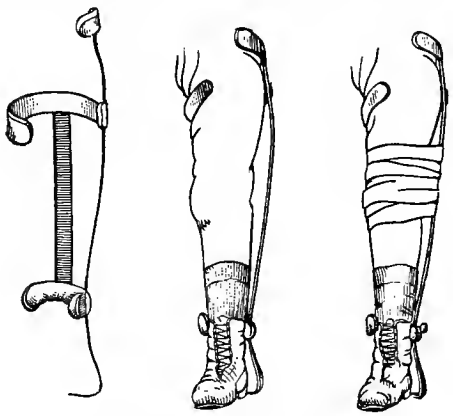

FIG. 380.—The Thomas knock-knee brace.

upper part of the thigh is a like band, and these bands are joined by a light bar of iron placed directly back of the middle line of the limb. At the top of the lateral bar is another padded band reaching about two inches to the front and an equal distance to the back of the lateral bar. The limb is bandaged to the splint by a figure-of-eight bandage, fixing the joint first to the posterior bar, and then laterally by passing the bandage around the limb and both bars. This corrected position is constantly maintained until the deformity is not only corrected, but remains so; then jointed retention braces may be applied and joint motion permitted.

John Ridlon.

KOESEN. A popular spa in the Prussian district of Merseburg, Germany.

LOCATION.—Koesen is very prettily situated about six hundred feet above the level of the sea. The surrounding country is hilly, and the little town is on the river Saale. The climate is mild, the air pure, and the scenery tempting. Season—May to September.

ACCESS.—Koesen is now reached by railroad by way of Naumburg.

ANALYSIS.—The *Johannesquelle* is a strong saline water. There is also a chalybeate spring, the *Mühlbrunnen*. Koesen is, however, chiefly known for the excellence and strength of its brine. Indeed, the principal spring, the *Soolquelle*, supplies so concentrated a brine, that it is necessary to considerably dilute it for bathing purposes.

INDICATIONS.—Rickets and scrofula in all their varied manifestations are principally treated at Koesen. But many women with chlorosis and diseases of the organs of generation, and sufferers from gout and rheumatism, are benefited by the Koesen baths.

ACCOMMODATION.—The hotels are small and only moderately good, but the thermal establishments are equipped with all modern appliances.

Edmund C. Wendt.

KOLA NUT. The seeds of the kola or cola tree, *Cola acuminata R. Br.*, order Sterculaceæ, a native of western tropical Africa. Kola is to the native of Africa what cocoa and maté are to the South American, and marvellous tales are told of the amount of work and fatigue that the African is enabled to endure when supported by the stimulating properties of this nut. It has been held in the greatest esteem from time immemorial, and is now looked upon almost as a vital necessity. It has been naturalized in other countries, and is valued by the inhabitants of the West Indies, Brazil, Mexico, and other tropical countries. In addition to its ordinary use, it has acquired a reputation as a specific in counteracting the depressing and debilitating effects of alcoholic intoxication. Experiments have been made with it in the French army which prove that it has decided stimulating properties, but is in no sense a food, and any benefit derived from its use may be traced to the caffeine which it contains.

The tree grows wild upon the western coast of Africa, from the Sierra Leone to the Congo, and reaches several hundred miles into the interior, where it follows the limits of the palm. It grows to the height of thirty or forty feet, and is said to resemble the chestnut in appearance. The leaves are six or eight inches long, pointed at both ends; the flowers are pale yellow spotted with purple; they are destitute of a corolla, but have a five-cut calyx, the segments spreading like the spokes of a wheel. The flowers are numerous, polygamous, in terminal and axillary cymose pannicles. In the male flower the stamens are united into a very short column, which bears the anthers in a single row, the cells of the anthers spreading apart. In the hermaphrodite flowers the anthers are subsessile in a ring surrounding the base of an oblong five-celled ovary. The ovaries are five in number and cohere together, each having a slender stigma but no style. Ovules are numerous, anatropal, attached in a double row to the ventral suture of each carpel. The fruit consists of two, sometimes more, separate pods or follicles, which split open on the inner side and contain several seeds about the size of horse-chestnuts, weighing from seventy-five grains to an ounce. The covering of the seeds is brownish-yellow in color, the substance is a white mass of cells filled with starch and containing the alkaloids which give to the plant its medicinal properties. The tree commences to yield fruit about the fourth year, and is at its best about the tenth year. The flowering is nearly continuous; and fruit and flowers may be present at the same time. There are two collections during a year, a tree averaging about one hundred and twenty pounds of fruit annually.

Several analyses have been made of the seeds, with slightly varying results, but all point to the caffeine as the principle to which its virtues are to be ascribed. The following table compares its constitution with tea, coffee, and cocoa:

	Cocoa (Mitscherlich).	Coffee (Payen).	Tea		Kola (Heckel).

The kola nut and its physiological action was treated in a thorough manner by Dr. Monnet in 1884, under the direction of Dr. Dujardin-Beaumetz, and an abstract of his thesis was published in the *Therapeutic Gazette* in the following year. The physiological and therapeutic action he sums up in the following conclusions:

1. Kola, by the caffeine and theobromine which it contains, is a tonic of the heart, whose pulsations it accelerates, while it increases its power and regulates its contractions.

2. A second phase of its action, similar to that of dig-

italine, proves it to be a regulator of the pulse, which revives under its influence, the pulsations becoming fuller and less numerous.

3. In consequence of its action upon arterial tension, diuresis is increased, and, consequently, kola can be employed to good advantage in cases of dropsy with cardiac lesion.

4. It might be deduced from observation that kola, which acts energetically upon cardiac contractions, and upon the contractility of muscles of organic life, would, on the other hand, have a paralyzing influence upon the striated muscles, when it is used in toxic doses.

5. It retards tissue metamorphosis and diminishes the excretion of urea resulting from decomposition of azotic substances, very likely by exerting a special action upon the nervous system.

6. It is a powerful tonic, through the principles which it contains, and its employment is indicated in cases of anæmia, in chronic affections associated with debility, and in convalescence from acute disorders.

7. It favors digestion, either by augmenting the secretion of the gastric juice (eupeptic), or by acting on the smooth fibres of the stomach, which it would render less atonic in cases of dyspepsia. Under its influence rebellious anorexia disappears and the digestive functions become more regular.

8. Finally, it is an excellent anti-diarrhœa remedy, and has rendered great service in chronic diarrhœa or sporadic cholera, although its action could not be explained physiologically.

Further use of the drug indicates that it does not possess any virtue that may not be ascribed to the alkaloids which it contains, and it has not secured a very firm foothold as a remedial agent. Its power to sustain fatigue has received more attention than its therapeutic properties. Among pedestrians and athletes its use has become very popular, and it is thought to prove very satisfactory to those who have used it. It has been suggested that the red substance that remains after the caffeine has been extracted by chloroform is a complex body, and exerts a peculiar stimulant action on the muscular and nervous tissues. A series of experiments have been made by E. Heckel (*Repert. de Pharm.*, October, 1892), to compare the action of caffeine and kola rouge or *kolanine*, from which he concludes that the action of the latter on the heart is more prolonged and due to the presence of caffeine in a "nascent" state. Surgeon R. H. Firth publishes (*Practitioner*, July, 1889) some very practical observations made upon British troops and natives under his control, and concludes that it is in no sense a food, and that its physiological action is explained by the contained alkaloids; when pure and not too old it has a peculiar stimulant action on the nervous system, temporarily strengthens the heart-beat, and increases the arterial tension; taken continuously during times of exertion and fasting, it possesses some power of warding off the sense of mental and physical exhaustion. This power, however, is not so marked as some observers have reported; in the convalescence from long sickness its value is not apparent, and its alleged antagonistic action to alcoholic sequelæ is not capable of proof.

As a therapeutic remedy it is of benefit in strengthening the weak heart, augmenting the general flow of blood and vascular tension, and promoting diuresis. Its tonic effect has also proved of benefit in disturbances of the nervous system and debility of the cerebro-spinal centres, and in the prostration accompanying and following severe fevers and protracted illness. As a remedy for diarrhœa, particularly of an atonic character, it has proved of decided value. The combination of the tannic acid and its tonic principles makes it of great service in this disorder. The preparations advised are the alcoholic tincture, the elixir, and the wine. The tincture is made by exhausting fresh kola with five parts of alcohol, and the wine by macerating the same proportions of kola in wine for a fortnight. The dose is from one to two or three teaspoonfuls three times a day. The elixir is prepared by diluting the alcoholic preparation with equal proportions of syrup. *Beaumont Small.*

KRONTHAL. A small spa in the Taunus district in Nassau, Germany. Kronthal is prettily situated near the wooded hills of the Taunus, not far from Frankfort-on-the-Main. The springs are mild saline, chalybeate ones, and are very agreeable to the taste on account of the large proportion of free carbonic acid. The Kronthal waters are much exported and are quite popular as tonic beverages. The spa is well suited to the milder forms of anæmia, dyspepsia, and neurasthenia. Many invalids go there for a so-called "after-cure." The climate is mild and pleasant. There are good facilities for excursions, promenades, and out-door amusements generally. A fine thermal establishment has been recently erected, in which the usual hydro-therapeutic appliances are found, also baths, massage, sprays, etc. The nearest railroad station is Kronberg, from which town Kronthal is reached in twenty minutes. *Edmund C. Wendt.*

LEPROSY. ETIOLOGY.—During the past five years the etiology of leprosy has received a great deal of attention, and the discussion has assumed somewhat of a public character. Among the most important contributions is that by[1] Zambaco, of Constantinople, who has had during ten years two hundred cases under constant observation. Although he made a careful study into the personal as well as the family history of these cases, he has not been able to establish a single fact which would prove the contagiousness of the disease. He cites a number of cases of individuals who have lived in the closest contact with lepers and have not become affected. He believes that it is contagious in certain localities and in extremely rare cases. He adheres to the theory of hereditary origin.

Dr. Heindiston[2] has cited several instances illustrating the hereditary character of the disease. He mentions the case of a child of a leprous mother, deserted soon after birth, and brought up by perfectly healthy people in a district where leprosy was not known. At ten years of age early symptoms became manifest, and at fourteen she was admitted into the leper hospital.

This case is quoted by Zambaco, and would therefore appear to be one of the best established instances of hereditary origin.

Dr. Danielsen has again affirmed that in his long experience he has never met with a single case of contagion.

Dr. Bevan Rake is doubtful as to the proof which has so far been produced in favor of direct contagion of leprosy. The question in his opinion is narrowed down to this: Can a healthy person more readily derive the bacillus from an infected human being, or from water, or from some host which contains the bacilli or its spores? On the other hand, Hansen, of Bergen, thinks the theory of the hereditary transmission untenable. He made careful personal investigations into the history and condition of the descendants of one hundred and sixty Norwegian lepers who settled in the States of Minnesota, Wisconsin, and Dakota. He traced out the history of the children, grandchildren, and even the great-grandchildren, and was not able to find a single case of leprosy among them. Dr. Phillips, of Jamaica, is of opinion that the disease is communicable by contagion, and Dr. Saunders, of Jamaica, is of the same opinion.

In the "Traité de Médecine," now being published under the direction of Charcot, Bouchard, and Broussais, the following conclusions are given regarding the etiology of leprosy: "The sole cause of leprosy is contagion, that is to say, the transmission of its bacilli by direct contact with a subject affected with ulcerative leprous lesions, or by the medium of different bodies upon which leprous secretions have been deposited."

Mr. Jonathan Hutchinson,[3] in an article on the "Leprosy Problem," arrives at conclusions of which the following are among the more important:

1. Leprosy is a well-specialized disease of which the bacillus of Hansen is the cause.

2. It is not modified by race, and it appears to have no allies.

3. It is not, for practical purposes, contagious.

4. It is endemic and affects both sexes.

5. It may occur at any age.
6. It is possibly hereditary.
7. It may be produced in immigrants or even visitors to leprous districts.
8. The poison which produces the disease gains access to the body in the form of food.
9. The evidence as regards the disease points to fish as being probably the article by which leprosy gains access to the human body.

He gives as a reason for the latter theory that in a very large number of leprous districts fish is one of the principal articles of diet.

To what conclusions may we arrive in view of the foregoing apparently contradictory opinions? Now that there is a general agreement that the disease is produced by the bacilli of Hansen, one might think that we could more easily arrive at a satisfactory conclusion.

The disease being of bacillary origin, must be communicated either by heredity or contagion. If by the latter, the virus must be introduced either by inoculation, in food, or through the atmosphere.

One cannot deny the possibility of hereditary transmission, although no instances have yet been reported which positively prove its hereditary character. The bacilli have never been found in the fœtus or in newly-born children, as has been the case in tuberculosis.

The cases cited by Zambaco and Heindiston are not conclusive, as in them the disease may possibly have originated in some other way. If Hansen in his investigations had discovered a single case in the descendants of the leprous immigrants in the Western States, where the possibilities of contagion were at a minimum, it would have gone a long way to prove that the disease may, at any rate occasionally, be transmitted from parent to child.

There can be no doubt that a tendency to this disease is thus transmitted. It is not at all impossible that the disease may be communicated in articles of food. That this is frequently the case is very doubtful.

The inhabitants of the Hawaiian Islands used the same form of diet after as before the introduction of the disease. If the food or drink then contained the virus, the germs must have accidentally become incorporated with them. Dr. Arning, on a most careful examination of all the surroundings of patients, water, food, soil, etc., was unable to discover the bacilli in any of them. They have never been found in fish or any other article of diet, as the bacilli of tuberculosis have been found in milk and the flesh of animals. In the parishes adjoining Tracadie, in New Brunswick, the inhabitants are of the same race, live under similar conditions as to food and climate, and yet do not suffer from the disease.

It is possible that further investigation into the subject may be rewarded by the discovery of the bacilli in other animals than the human being. The theory of contagion by inoculation, or by prolonged and intimate contact, seems to best satisfy all the facts. By this theory alone can the outbreak in Tracadie or in the Sandwich Islands be understood.

The fact constantly brought forward of individuals living in the closest contact for a lengthened period with lepers, and remaining free from the disease, can be accounted for on the ground of natural immunity. We have instances of individual immunity in as contagious a disease as small-pox.

It is true that leprosy appears to be but slightly contagious, and requires a soil which is only produced by certain modes of living, the use of certain food, and in certain races. It is also true that there are occasional cases of individual susceptibility in the most highly civilized races and in the highest classes of society.

On September 30, 1884, Dr. Arning inoculated a criminal with fresh matter from a leprous tubercle. Local inflammatory action ensued which lasted six months and disappeared. In September, 1887, tubercular leprosy made its appearance, and the patient has since succumbed to the disease.

Dr. Morrow, who visited the Sandwich Islands in 1889, excised some of the tubercles of this patient and found bacilli in them. Dr. Arning does not consider the case a positive proof that the disease originated by inoculation, as there existed other possible channels of infection. So far all attempts to inoculate animals have failed.

Pathology.—Subsequent investigations have confirmed the truth of the discovery of Hansen and Neisser. The bacilli are the active cause of the various lesions peculiar to the disease.

Leloir[4] gives in the following summary the differences between the bacilli of leprosy and those of tuberculosis: "The bacilli of leprosy are especially distinguishable from those of tuberculosis because in the colored sections lepromes always maintain an immense quantity of bacilli, while tuberculomes always contain much fewer, and most usually they are very few in number."

The size of the lepra bacillus is more uniform and more rectilinear than the tubercle bacillus (Cornil). They are shorter, thinner, and less pointed than those of tuberculosis (Hansen). The bacilli of leprosy are also more easily colored than those of tuberculosis. A much longer period is required to decolorize them by nitric acid. The tubercular bacillus colors only in alkaline coloring liquids; that of leprosy takes color in neutral or acid coloring liquids (Neisser). For the purpose of distinguishing, for example, the bacilli of leprosy from those of tuberculosis, if they occur together in an organ, the sections are colored with simple fuchsin for half an hour and decolorized with an acid. By this proceeding the lepra bacilli alone remain colored (Cornil and Babes). Dr. Thin[4] has made a careful study of the question as to whether the bacilli are intra- or extra-cellular, and concludes that there is no evidence that the bacilli can live and multiply outside the cells. He thinks this accounts for the chronicity of the disease and the comparative rarity of contagion.

Boinet[6] arrives at the following conclusions with regard to the existence of giant-cells in leprous tissue: "There exist in the lepromes giant-cells like those of inflammation and tuberculosis. They appear to be the result of an inflammatory process and in this particular case the giant-cells do not seem to exercise any distinctive action on the bacilli of leprosy."[7] Of the various parts of the body the bacilli are most frequently found in the skin. The mucous membranes, except those of the large intestines, are generally exempt. The lymphatic glands are almost invariably affected. They are not found in the brain or spinal cord, but they exist in large numbers in the smaller branches of the nerves.

Dr. Bevan Rake,[5] who has made many valuable contributions to the study of this disease, has published the result of his inquiries into the connection between kidney lesions and the skin changes in leprosy. Out of forty-one cases of nephritis he found bacilli in but two. He also found that cases of kidney lesion ran a more chronic course than those of the other results or complications of leprosy.

Dr. Schultze[8] has published the results of electrical and other examinations into the neuritis of leprous subjects. He found the same alteration of motor power and the same electrical reactions as exist in the neuritis arising from other causes.

Diagnosis.—The diagnosis between leprosy and syringo-myelia was made the subject of a paper read by Dr. Morrow at the meeting of the American Dermatological Association, 1888, and has recently been studied by Marestang.[9]

The latter author has arrived at the following conclusions:

1. Leprosy and syringo-myelia are two distinct diseases.
2. Syringo-myelia is the result of medullary change (chiefly gliomatous), while anæsthetic leprosy is the result of neuritic changes
3. The points of distinction clinically are as follows:

(*a*) In syringo-myelia there is loss of thermo-anæsthesia and analgesia, with integrity of the tactile sensibility. This disassociation of sensory conditions is not found in leprosy.

(*b*) In syringo-myelia the surface muscles of the face are unaffected, there is absence of discolorations on the skin,

and the hair remains normal, but there is deviation of the vertebral column.

In leprosy tactile sensibility is abolished, and there are atrophy and paralysis of the muscles of the face, thickening of the nerve-trunks from infiltration, the presence of light-colored patches on the skin, resorption of the fingers, excessive alteration of the nails, complete or partial loss of hair, and the presence of the bacillus of Hansen in the discharge from the ulcerative lesions.

Zambaco,[1] at the Académie de Medecine, Paris, 1892, expressed the opinion that Morvan's disease is a form of leprosy, as also is one variety of syringo-myelia. The writer could not gather from the discussion that the bacilli of Hansen had been found in either of these diseased conditions.

Prognosis.—Several cases of cure, or rather cessation of the symptoms, have been recently reported: one by Dr. G. H. Fox, which will again be referred to; Sandreczky[9] also mentions a case in which the lesions disappeared; finally, Dr. Kaurin gives the history of two cures, and Dr. Muro, of St. Kitt's, relates the history of one.

The number of apparent cures, however, is small compared with the whole number of cases. The disease has therefore lost little of its dreadful fatality, notwithstanding the many new methods of treatment adopted.

Treatment.—Dr. Unna, of Hamburg, in 1885, published a method of treatment and related one apparently successful case. He made external applications of pyrogallol, chrysarobin, resorcin, and ichthyol, and gave ichthyol internally. From Dr. Thin's work I would infer that Dr. Unna's patient died in South America, whether from leprosy or not is not known.

Dr. Duckman[12] relates an advanced case of disease treated after Unna's method with apparent success. According to Dr. Thin, however, the patient died in 1889, probably from leprosy.

Dr. Duckman used ten per cent. pyrogallol ointment for the forearms and hands, and ten per cent. chrysarobin upon the other parts of the body except the face. On the latter he used a plaster of salicylic acid and creasote. Ichthyol was given internally.

Dr. Blue, of New Orleans,[13] has reported a number of cases treated according to Unna's method. He states that pyrogallol, resorcin, and salicylic acid were not at all satisfactory when applied to the face, but that they were useful on other parts of the body. He gave ichthyol up to six grains a day with negative results.

Dr. G. H. Fox[14] has reported a case of apparent cure in which the principal remedy used was chaulmoogra oil. The patient, a young man of New England parentage, was born in the Sandwich Islands, and symptoms of leprosy having developed, he came to America, and after a time (1883) placed himself under Dr. Fox's care. After other methods of treatment failed he was put on chaulmoogra oil in gradually increasing doses, until he took sixty drops each day. In time the lesions gradually disappeared, and in 1885 he wrote to Dr. Fox from California: "There have been no more symptoms of the disease in any shape. I have enjoyed almost perfect health in every way, and were it not that I still have numbness of the hands I would not believe that there could be anything the matter with me. I take about a hundred drops of the oil daily and it does not disagree with me." In 1887 and 1889 he reported himself as being quite well, and Dr. Fox has recently informed the writer (February, 1893) that the patient is still in good health.

The favorable result, as Dr. Fox states, is largely due in this case to the change of climate as well as to the remedy used.

Dr. Zariago (de Valence) gives chaulmoogra oil in large doses with decidedly beneficial results. He speaks highly of Unna's method of treatment in the early stages of the disease.

Dr. Falcoo[16] gives gynocardic acid in one decigramme pills with bitter extract. He begins with two pills daily and increases the number to twenty. At the same time he uses a pomade of gynocardic acid and vaseline.

Gurjun oil has been used with apparent benefit by some physicians.

The following quotation from the "Journal of the Leprosy Investigation Committee," January, 1890, will give in brief our present knowledge with regard to the action of tuberculin: "The authors consider that these differences (of reaction) prove for us, (*a*) whether an affection is leprosy or tuberculosis, (*b*) whether at the time being leprosy is associated with tuberculosis, and (*c*) whether a suspicious tropho-neurotic disease be leprous or not. They observe that it remains to be seen whether the remedy can cure leprosy, produce a durable improvement, or prevent its further development." Tuberculin does not seem to have any positive effect in the cure of the disease. Dr. Rake has reported the case of a negress, in whom vaccination produced an amelioration of symptoms. Several cases have been recorded where the presence of an intercurrent affection, such as erysipelas, pneumonia, etc., has exerted a favorable influence on the course of the disease.

Prophylaxis.—From a brief survey of the literature one is impressed with the idea that leprosy has made considerable progress during the last five years.

Dr. P. S. Abrahams[18] publishes the following statements with regard to some of the British Dominions: The disease is certainly on the increase at the Cape of Good Hope.

The number of cases has increased in the Trinidad Asylum, as shown by Dr. Bevan Rake.

The total number of cases in the Barbadoes has increased from 96 in 1871 to 120 in 1881.

In New Brunswick there has been a slight diminution.

The disease has appeared in British Columbia, but is limited, as Dr. Milne, of Victoria, informs me, to the Chinese population.

The present number of lepers in the United States is placed at about two hundred, a decided increase.

Zambaco makes the following suggestions as to prophylaxis:

1. All cases of the disease to be placed in a special hospital, where they can receive proper attention and medical treatment.

2. To prevent marriage in all cases where the disease is present or even suspected.

3. To improve the character of the food and surroundings of the people.

4. To carefully inspect and supervise the children of leprous parents.

Dr. Bevan Rake, who, with Zambaco, is still sceptical on the subject of contagion, also recommends isolation.

It will thus be seen that in the prophylaxis of the disease there is a unity of opinion between the contagionists and non-contagionists on the importance of the complete separation of the diseased from the healthy.

During the past five or ten years much progress has been made in this direction.[19] In 1884, the government of the Cape of Good Hope passed a Leprosy Repression Act. In Norway, segregation was made compulsory in 1885.

Under an act to facilitate the segregation of lepers in the Hawaiian Kingdom, 821 lepers had been removed to the asylum, between July 17, 1887, and March 12, 1889. For some years in New South Wales lepers have been kept in a lazaretto near Sidney, and quite recently a bill has been passed by the New South Wales Legislature to empower the authorities to compulsorily segregate lepers.[19] In Sau Francisco also a stringent act has been adopted.

In many parts of the world, however, as Dr. Thin observes, great carelessness is still shown in this matter.

LEVULOSE ($C_6H_{12}O_6$.). This form of sugar has, within the past year, been advocated as an article of diet for diabetic patients. Its administration does not augment the amount of sugar in the urine, as it is thoroughly oxidized in the system, and acts as food by building up the body and supplying vital energy and strength. A preparation under the name of *Diabetin* has been placed in the market, which is said to be a perfectly pure levulose. It is a dry crystalline powder, easily soluble, and possessed of a remarkably sweet taste.

Levulose exists in honey and in most fruits and vegetables. It may be formed from cane sugar by heating with dilute acids, and is also produced by the action of yeast on pectase, the ferment peculiar to fruits. It is distinguished from the ordinary forms of sugar or dextroglucoses by its property of turning the plane of polarization to the left, lævo-rotation, from which its name is derived. It generally exists with dextro-glucose, and is with difficulty obtained pure. It exhibits the same chemical reactions as other sugar, but is more easily altered by heat and acids. A large percentage of dextro-glucose may be present without altering its rotatory action, as its power of polarization is much greater than that of the dextro-rotatory sugar. *Beaumont Small.*

LIPANIN. A fatty compound formed by the addition of five or six per cent. of oleic acid to fine olive-oil. It has been proposed by Von Mehring as a substitute for cod-liver oil. Its use was suggested by the theory of Buckheim that the beneficial action of cod-liver oil was due to the fatty acids it contained. The proposed substitute is more palatable and is easily retained by the weakest stomach, and when desired may be readily formed into an emulsion. It is freely absorbed, and undoubtedly is a nutrient of some value. No diarrhœa or intestinal disturbance has been traced to its use. The dose for children is one teaspoonful before meals; for adults, one tablespoonful. *Beaumont Small.*

LITHÆMIA. In the treatment of the uric-acid variety of lithæmia, the so-called uric-acid diathesis, as well as in true gout, *piperazine* has been extolled and freely advertised, in 1892, as a specific for that disordered state of the system. The remedy, a whitish powder of pungent taste, is prescribed in five-grain doses dissolved in carbonic-acid water, with or without bicarbonate of soda, and given three or four times in twenty-four hours. I have found it to be a fairly good palliative for an acute attack of gout, but a specific by no means, nor as good as Laville's liqueur antirheumatique, the active principles of which are colchicine and colocyntine. Laville's preparation I have often prescribed for acute attacks of gout, and found that twenty to thirty drops taken every three hours during the day, for a week at most, afford quick relief, and remove all acute symptoms effectually in almost every case. In cases of uric-acid diathesis neither Laville's liqueur nor piperazine is ever indicated, but the plain and cheap *bicarbonate of soda*, with a little lithion and chloride of sodium, is all that is required when the patient needs a mineral water.

Of German observers Dr. E. Pfeiffer, Dr. Mordhorst, of Wiesbaden, and Professor Ebstein, of Göttingen, have studied the question of gout and lithæmia, and the proper diet and medication for those afflicted with these disorders, and have written probably more about it of late than anybody else. The Wiesbaden doctors particularly, who undoubtedly see and treat a great many gouty patients, have apparently proved that *bicarbonate of soda* is the remedy of all others which will promptly dissolve, and effectually keep in solution, the uric acid. They order now their patients to take it, dissolved in a mineral water that goes by the name of "Wiesbaden Gichtwasser" and is prepared by putting extra quantities of bicarbonate of soda and lithion into the natural Wiesbaden Kochbrunnen. The patient takes about a quart of this water per diem, in divided doses, and with excellent results, as has been proved by recent statistics.

The following analysis of the Wiesbaden Gichtwasser has been published: One thousand grammes of the water contain:

Natr. bicarbon	7.560
Natrii muriatic	6.828
Calc. bicarbon	0.266
Magnes. bicarbon	0.177
Lith. chloric	0.023
Potass. chloric	0.182
Carbonic acid	9.296

These are the principal ingredients of the water, and the therapeutic effects of the same are mainly produced by the relatively large amount of the soda and salt, and to only a small extent by the other salts. That an alkaline water thus prepared and drank in sufficiently large doses daily, and for a considerable period, will prove of excellent effect in gout and uric-acid diathesis I am ready to testify to from the observation of a large number of cases of that kind. The well-known Selters, Vichy, and Fachingen waters can readily receive additional quantities of soda and salt to bring them up to the required standard of about 3 ij. of each salt to a quart of water, and will then serve the same purpose as the Wiesbaden water.

Leonard Weber.

LLANDUDNO. A modern and fashionable watering-place in Wales. The climate is good, owing to its sheltered position. It is more of a summer resort and sea-bathing place than a recognized winter station. It is situated under the promontory of the Great Orme's Head, and extends for over a mile along the shore, between the bays of Conway and Llandudno. The sanitary condition of the settlement is good, the rate of mortality being about nineteen per thousand per annum. The winds coming over the water are generally tempered, but violent cold gales at times keep all invalids indoors. Dr. Yeo ("Climate and Health Resorts") speaks of this place as follows:

"Llandudno has pretensions also as a winter resort, especially for invalids who can support a certain amount of windy weather. Its annual rainfall—32.36 inches—is somewhat below the average rainfall of England and Wales, which is 35 inches. The mean humidity of the air in winter is 82°, so that it has a drier winter atmosphere than some of our southwest coast resorts; this is partly due to the porousness of its subsoil, which is mostly gravel and sand.

"During the five winter months (November to March), from observations extending over five years, it would appear that the mean winter temperature is 43.5°; the mean maximum, 48.3°; the mean minimum, 38.8°; the mean daily range, 9.5°; the mean monthly range, 28.3° F. North and east winds blow on 44 days, south and west winds, 107 days. There were 83 rainy days, and a rainfall of 15.96 inches.

"Nothing, perhaps, could show better the character of our (*i.e.*, the English) winter climate than the fact that a place claims to have attractions as a winter resort, where, on an average of five years, there have been eighty-three wet days out of one hundred and fifty-one—more than one-half!"

Llandudno is two hundred and thirty-six miles distant from London.

The hotel accommodation is good, and the usual amusements are provided. The drinking-water is said to be excellent. There is a fine sandy beach.

Edmund C. Wendt.

LOSOPHANE (Tri-iodo-meta-cresylic acid). A new antiseptic preparation, obtained by the action of iodine upon oxy-toluylic acid in the presence of an alkali. Its formula is $C_6HI_3OHCH_3$, and it is said to contain eighty

per cent. of iodine. It forms in white needles, insoluble in water, slightly soluble in alcohol, and readily soluble in ether, benzene, and water. At 140° F. it is freely soluble in fatty oils.

It is particularly recommended in parasitic skin affections. It may be used in tinea tonsurans, scabies, pityriasis versicolor, also in prurigo, in chronic eczema, acne, and sycosis. It is contra-indicated in all acute inflammatory conditions of the skin, as it is liable to increase the irritation and intensify the disease. The remedy may be applied in solution of the strength of one per cent., or in an ointment of one to three per cent.

Beaumont Small.

LOWESTOFT. A popular seaside resort on the Norfolk coast. It is situated on the most easterly point in England, at a distance of about ten miles from Yarmouth. The beach is much used for bathing, although it is only partly sandy and in part shingle. The little town is prettily built on the cliffs overlooking the sea. The air is claimed to be particularly pure and bracing at Lowestoft, but the place does not escape the humidity and abundant rainfall common to English resorts. The drinking-water is good, and the sanitary arrangements satisfactory. The death-rate is about eighteen per thousand. The hotel and boarding-house accommodation is moderately good. *Edmund C. Wendt.*

LUNGS, ANATOMY OF THE. HISTORICAL.—The first account we find of the structure of the lungs is that given by Hippocrates,[1] and is very incomplete. He compares them to a sponge interspaced with numerous small vessels. Aristotle[2] also gives to the lungs a spongy nature, the canals receiving blood from the great vein. Celsus[3] also describes the lungs as being spongy. Galen[4] had but little better idea of their structure; he describes them as being made up of lobes, liver-like in substance, and containing many vessels. Vesalius[5] describes the lungs as being divided into lobes, and says in regard to their structure that "the substance of the lung is soft, spongy, thin, light, airy flesh, as if formed of frothy blood, or bloody froth, and crowded with many branches of vessels."

We now come to the time when Harvey[6] announced his discovery of the circulation of the blood; this had its effect on all anatomical research. Malpighi,[7] profiting by this discovery, proved by means of injections that the air and blood were not contained in the same channels, but had separate systems of vessels, and that these did not communicate with each other, but did communicate among themselves. He also saw the circulation of the blood in the vessels of the lung of a living frog. He recognized the presence of air-vesicles, and described them as opening into the trachea and communicating with one another. He also compares the lung to a sponge. Bartholin[8] defended the views of Malpighi. The next writer of note is Willis.[9] He is wrongly quoted by Williams in Todd's "Cyclopædia;" he places Willis among those who describe the air-vesicles as communicating with one another. What he does say, directly opposite to the view of Malpighi, is, that the bronchial tubes give off numerous small branches which bear on their distal extremity little bladders, thus giving the lung the appearance of a bunch of grapes. Helvetius[10] returned to the older idea and maintained that the lung was spongy in its nature. He denied that the spongy tissue of the lung was formed by the expansion of the bronchial tube, but asserted that the bronchus simply penetrated into the spongy tissue. His description of the lung is not very clear. Soemmering[11] describes the lungs as made up of small, irregular polygonal cells grouped together into lobules. The cells of the lobule communicate, but those of one lobule do not communicate with those of adjoining lobules.

Early in the present century, Reisseissen[12] published a very important paper, in which he advanced views quite opposite to those accepted by the anatomists of his day. His method consisted in pouring mercury into a bronchus and, by applying gentle pressure, forcing it on until it appeared beneath the pleura. He describes the bronchi as dividing into branches which in turn divide quite rapidly, becoming at the same time much smaller, until eventually each small branch ends in a single rounded extremity. This was apparently a revival of the theory of Willis. Magendie[13] wrote two important papers on the lungs. In the first he denies that the bronchi terminate in air-vesicles, but affirms that the air-cells of one lobule communicate with one another, but do not communicate with those of adjoining lobules. In his second paper he states that those grape-like structures described as hanging on to the end of a bronchus do not exist in nature, but are to be found only in books. His conclusion is that the lung is made up of "spongy tissue formed by the arrangement of the vessels, which have between them small spaces into which the air penetrates freely."

In 1832 Bazin[14] wrote supporting the views of Reisseissen, and was followed a few years later by Lereboullet,[15] who in quite a lengthy essay also supported Reisseissen. Addison[16] failed to find "any tubes ending in culs-de-sac; on the contrary, I always saw air-cells communicating with one another in every section I made." He describes the bronchi as dividing, within the lobule, into numerous minute branches which terminate in "branched air-passages and freely communicating air-cells." Huschke,[17] however, writing about the same time, described the bronchi as ending in fine branches, which bore on their free extremity small sacs which did not communicate with one another.

Rainey[18] wrote several excellent memoirs on the lung. He says "they are made up of bronchial tubes, bronchial intercellular passages, and air-cells." These air-cells communicated with one another, and with the bronchi or bronchial intercellular passages, by means of large circular openings. Moleschott[19] published an excellent brochure in which he combats strongly the opinion of those who hold to the communication of one vesicle with another. In no instance did he find the bronchi forming anastomoses; he also distinctly states that the air-vesicle contains no opening except that by which it communicates with its proper bronchial tube.

Rossignol[20] gave us a very valuable treatise on the structure of the lungs. He introduces the term "infundibulum." According to this author the bronchi give off numerous branches which cross each other repeatedly in all directions, but do not communicate; from the ultimate division of the bronchial tube arises a dilatation in the form of a funnel, which he terms "infundibulum." The walls of each infundibulum are lined with numerous air-cells or alveoli. Rossignol compares each infundibulum with its alveoli to the lung of the batrachians, and says: "The human lung looked at from this point of view can be defined as the assemblage or concentration of innumerable small lungs, held together by means of a common bronchial tree." In an inaugural dissertation written by Adriani,[21] he adopts the nomenclature of Rossignol. He also describes alveoli as existing on the walls of the bronchial tubes just before they dilate into infundibula. He takes strong exception to Rossignol's statement that there are no communications between adjoining alveoli, declaring it to be without doubt false, and describes minute openings by which adjoining infundibula communicate.

Kölliker[22] gives quite a valuable description of the finer structure of the air-passages. He considers the term "infundibulum" introduced by Rossignol unnecessary, and says, that "all the vesicles belonging to one lobule open, not into ramifications of the finest bronchial twig going to it, but into a common space from which the air-vessel is afterward developed."

The "Cyclopædia of Anatomy and Physiology"* contains an article on "Respiration" by Williams, in which he has embodied some of his personal investigations. He describes each lobule as being sacculated and receiving a single bronchial tube; this tube gives rise within the lobule to small branches which subdivide to the third or fourth order, and from these latter branches the air-

* The Cyclopædia of Anatomy and Physiology. Supplementary volume. London: Robert B. Todd, editor.

cells arise. He discards the term "infundibulum," and uses in its place that introduced by Rainey, "intercellular passage." Mandl [23] describes the bronchial tubes as ending in terminal cavities which have numerous depressions in their walls, the "vesicles." He compares the terminal cavities and their vesicles to the lung of the frog.

In 1860, Waters [24] published a most excellent essay on "The Human Lung," in which he describes the "ultimate pulmonary tissue" as being made up of elongated air-sacs arranged in groups, called by him "lobulettes," which spring from the enlarged end of a terminal bronchial twig; the air-sacs bear on their sides and ends depressions varying in number, the alveoli. He failed to find any communication between the air-sacs. On this point he says, "I have never found, either in the lungs of man, or of the dog, or cat, or pig, or sheep, or of any other mammal I have examined, any lateral orifice of communication between the different sacs of each lobulette."

Henle,[25] in his systematic work on anatomy, gives a very good article on the lungs. He describes communications between air-cells, but considers them anomalies. He found them in the lungs of old people, and attributed them to the result of atrophy and absorption of the lung-substance. Delafield [26] advocates the theory of communication between air-cells. He says: "The air-passages seem to be made up of a succession of large vesicles which open into each other, or of an irregular larger canal made up of vesicles into which other vesicles open from all sides." He also describes anastomoses between the air-passages. Roosevelt [27] agrees with Delafield in regard to the communication of the air-cells. In other places [28] I have described some of my own researches on the lung.

Besides the authors quoted at length, I will refer the reader to the works of Milne-Edwards,[29] and to that of Ewart.[30] Those who are interested in the development of the lung should not neglect to read the article by His.[35]

General Histology.—For the structure of the trachea I will refer the reader to the text-books on anatomy, mentioning especially Quain (tenth edition).

At the hilus of the lung we find the artery, vein, and bronchus lying in quite close apposition, and it is only at this point that we find them in such close relationship. The arrangement differs on the two sides; on the right side the bronchus lies behind, the artery in the centre, and the vein on the outside; the bronchus occupying a higher level than the other two vessels. On the left side the vessels have the same order, but the artery occupies the higher plane.

Taking up now each set of vessels, we will consider first the bronchus.

About on the level of the fifth dorsal vertebra the trachea bifurcates into the right and left bronchi, which pass to their respective lungs. Of these two bronchi the right is the shorter and wider, and is usually described as having a more horizontal direction than the left. Aeby,[31] in his admirable monograph, has shown, however, that it is the more oblique. The left bronchus is longer, but at the same time smaller in diameter, than the right; its lower termination being about twenty-five millimetres below that of the right bronchus. The shortness of the right bronchus is due to the fact that, just before it penetrates into the depth of the lung, it gives off a branch which supplies the upper lobe of the right lung. This branch is given off above the point where the pulmonary artery crosses the bronchus on its way into the lung. On the left side we find no corresponding branch in man.

Below the point where the pulmonary artery crosses the main bronchus, the arrangement of the bronchi is quite similar on each side. This peculiarity of the bronchi leads to the formation of three lobes for the right lung, but only two for the left lung. Aeby calls those that branch above the point where the artery crosses, eparterial; those below, hyparterial bronchi; he reasons that as the eparterial bronchus is not present on the left side, the lobe to which it is distributed is also absent, and that the upper lobe of the left lung and the middle lobe of the right lung are homologous. Occasionally in man the eparterial branch arises directly from the trachea; this point of origin is constant in sheep and in the ox. Some of the lower animals possess eparterial branches on both sides, and in others no eparterial branches are found. Monkeys have an accessory lobe, termed by Owen [32] the azygos lobe; this is supplied by an accessory bronchus, which arises from the right bronchial trunk near the point where the first branch is given off.

Immediately after penetrating into the lungs the bronchi undergo division, not in a dichotomous manner; neither is the arrangement axial, but rather arborescent. Aeby,[31] by his investigations, proved conclusively that the old idea of dichotomy was erroneous; and while at first I was inclined to the view of an axial arrangement, more careful investigation of the subject satisfied me of the untenableness of this view.

The bronchi, in their finer structure, have the same arrangement as the trachea up to their entrance into the lung. With the division of the bronchi we find changes in the structure. The cartilage which has been in the form of incomplete rings is now found in the form of angular plates, which are placed at longer and longer intervals, until at last it is only found as a small plate at the fork of the smaller branches. Bronchi which have a diameter of one millimetre, and under, have no cartilaginous plates. At the same time that the cartilage begins to disappear, the smooth muscle-fibres which have been in the form of rings gradually spread out into an uniform layer, which diminishes in thickness with the diminution in the calibre of the bronchus. Beyond the terminal bronchus the muscle-fibres are not found. In the larger bronchi the mucosa is arranged in longitudinal folds and consists of at least two layers, the innermost of which is made up of ciliated epithelium and scattered goblet-cells. In the finer bronchi these disappear, and we find in their place a single layer of respiratory epithelium. Outside the cartilage, and extending the whole length of the bronchi, there is found a layer of connective tissue which forms a sheath surrounding the bronchi and contains elastic fibres, and in which the vessels and nerves run.

When the divisions of the bronchus have reached a diameter of about 0.5 mm. they break up into the proper parenchyma of the lung. The last division of the bronchus before this breaking up takes place is called the terminal bronchus, and it forms at the distal extremity a club-shaped cavity.

At this point the structure of the lung changes, and what lies beyond this has been a much disputed point, as I have shown in my account of the history of the subject. As a preliminary description, I will quote the following from a previous paper:[28] "The last division of the bronchus, before breaking up into the parenchyma of the lung, is known as the terminal bronchus, and from this arise a number of passages which widen out into an expansion. From this other passages lead out which open into a central cavity set about with small irregular cells. A good idea of this arrangement may be obtained if we compare it to a Pompeian house. The passage leading off from the terminal bronchus is the 'vestibulum,' which opens into the 'atrium.' From this arises the 'faux' or air-sac passage, which leads into the 'peristylum' or air-sac. This air-sac is set about with 'cubicula' or air-cells.

"From this description it will be seen that the air-sacs do not communicate directly with the terminal bronchus, as is usually described, but between each air-sac and terminal bronchus there is a cavity constant in all parts of the lung, which I shall term atrium. The communication between the atrium and the bronchus I shall call vestibulum; that between the atrium and air-sac, air-sac passage, or, simply sac-passage." (Fig. 381.)

The terminal bronchi do not have a smooth cylindrical surface, but we find projecting from all portions small cells (Fig. 381), the air-cells of the bronchus, which have an average diameter of 0.047 mm. The opening by which these cells communicate with the

bronchus is surrounded by the smooth muscle-fibres lining the bronchus. In a section of the lung the terminal bronchi may be recognized by their diameter, by their walls being thicker than that of the surrounding parenchyma, by the presence of smooth muscle-fibres, and by their having a lining of cylindrical epithelium.

Leading out of the dilated end of the terminal bronchus we find from three to six openings, the vestibules. These are circular in outline, or nearly so; they are surrounded by the muscle-fibres which line the bronchus, and have an average diameter of 0.2 mm. These openings do not all take the same direction; usually one of them appears as if it were a continuation of the bronchus, while the others open out at various angles or may take a course nearly recurrent to that of the bronchus. As these openings are surrounded by smooth muscle, should the section lie in such a plane that we look directly into a vestibule, it will appear as a quite small terminal bronchus, but can be distinguished from one by its size. I have already stated that the smooth

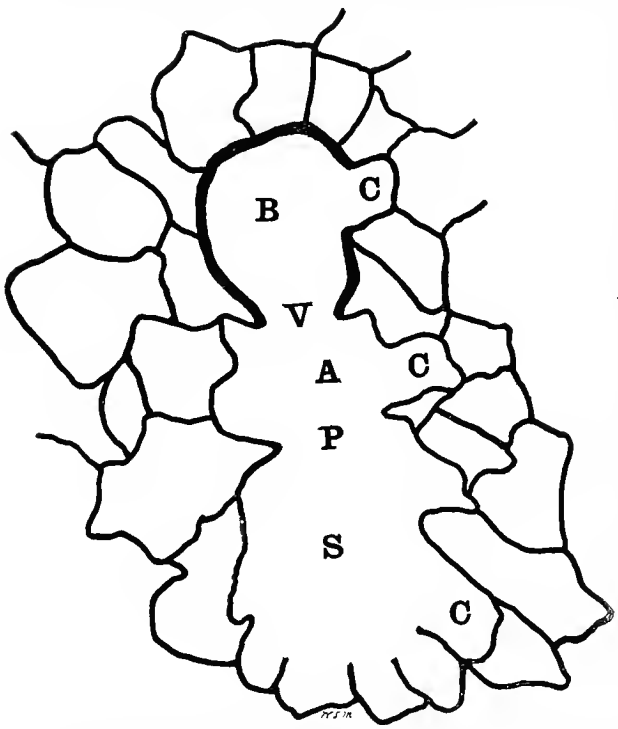

FIG. 381.—Camera Tracing of a Section through the Terminal Bronchus, Atrium, and Air-sac. Enlarged about 65 diameters. *B*, terminal bronchus; *A*, atrium; *S*, air-sac; *V*, vestibule: *P*, sac-passage; *C*, air-cells arising from terminal bronchus, atrium, and air-sac.

muscle-fibres do not extend beyond the terminal bronchus. That this ring surrounding the openings of the vestibules is the last found is shown in sections which lie in such a plane that a vestibule is cut at right angles. In such a section we find the bundles of muscle-fibres cut transversely, lying on either side of the mouth of the vestibule, but not in the least entering into the formation of the walls of the cavity lying beyond.

The cavity into which the vestibule opens I have called the atrium (Figs. 381, 382, 383, 385, *A*). This is irregularly spherical in shape, about half the size of a terminal bronchus, and has leading out from it three to six openings; of these, one is that of the vestibule, and the remaining openings lead into the air-sacs with which it communicates. There are also numerous projections from its surface, the air-cells. The walls of the atrium differ in no respect from those of the air-sacs.

If we make a complete injection of the air-passages with wax and corrode in hydrochloric acid, we shall obtain a mass which cannot be pulled apart; if now we break off a small portion from the completely injected part and pick it to pieces under a dissecting microscope, we may obtain casts of the atria which present several freshly broken surfaces. These indicate the points of attachment of the air-sacs, and also their attachment to the bronchus. The presence of these broken surfaces has been misinterpreted by a recent writer, and used as an argument for the communication between air-sacs. That such is not the case will, I think, be readily understood from the above description.

In Fig. 382, I have represented a terminal bronchus to which are attached five atria. The air-sacs communicating with them have been removed. The specimen was prepared by cutting a small block from the lung of a dog (treated by the corrosion process) into serial sections, and then reconstructing by Born's [33] method a terminal bronchus and the parts attached to it. Two models were made, in one of which the air-spaces were cut out and the plates piled together. This gave an exact model of the air-spaces. At the same time the plates were piled together the pieces cut out were piled also, and I thus obtained the second model—a "corrosion" of the first. It is this corrosion deprived of its air-sacs that is figured. The sections were cut 20 μ thick, and the power used was one hundred diameters.

The air-sac passages connecting the atrium with the air-sacs are somewhat smaller than the vestibule, having an average diameter of 0.143 mm. The air-sac passages (Figs. 382 and 383, *P*) can always be distinguished from the vestibule by the absence of smooth muscle-fibres.

The air-sacs present a great diversity of forms; they are very irregular and adapt themselves to the space they have to occupy. As seen in sections of the lung, they vary in diameter from 0.313 mm. to 0.511 mm. Fig. 383 shows a corrosion model, prepared in the same manner as Fig. 382, of an atrium with a single air-sac attached, the others having been removed.

Fig. 384 shows an air-sac removed from its atrium; the irregularity of form is well shown. Some air-sacs have a deep partition extending into them, nearly dividing them into two. The irregular contour of one air-sac fits into corresponding irregularities in adjoining air-sacs, making it impossible to pull complete wax or Wood's metal corrosions apart. The walls of the air-sacs are quite thin, and are made up principally of the capillary network of the blood-vessels and connective tissue. Mall [35] has shown the presence of "reticulum" in the walls of the air-sacs. In sections of lung lying parallel with, or perpendicular to, the pleura, the large irregular-shaped openings bounded by thin walls are the air-sacs. The small openings grouped about them are the air-cells.

The air-cells are about one-fourth the size of the air-sacs; their walls are thin and have the same structure as those of the air-sacs. Air-cells are found in three situations: arising from the bronchus, from the atrium, and from the air-sacs (Fig. 385, *C*). Those arising from the air-sacs are the more numerous, the entire periphery of the air-sacs being covered with them. The air-cells arising from the air-sacs and atria have the same average diameter of 0.113 mm., while those air-cells which are found on the bronchus are smaller, having an average diameter of 0.047 mm.

It is not uncommon to find in sections made parallel to the pleura that the plane of the section is such that it divides longitudinally as a vestibule opening into an atrium, and in rare instances it may pass through all the parts. Fig. 381 is an example of such a section. Usually, it is quite difficult to determine the atria and air-sacs, unless we have a complete series of sections to examine. I have already mentioned several points of distinction, but for general purposes attention to the following points will help one to decide: The bronchi may be recognized by their containing smooth muscle-fibres, and by their diameter; lying in more or less of a circle about the bronchus may be seen three, four, or five openings, nearly circular in outline and separated from the bronchus by a number of smaller openings; the first are the atria, the

second are air-cells. Lying peripheral to these may be seen large irregular openings, the air-sacs, and grouped around each a number of smaller openings, the air-cells.

A much disputed question in the histology of the lung is whether there exist communications between the air-sacs. As I have shown in my brief account of the History of the subject, the opinion of the older authors was that such communication did exist. For a long time no one doubted the point; then it was denied, and for a considerable period the question was vigorously discussed on both sides; but gradually the view that there were no communications prevailed. The two most recent writers on the subject in this country, however, have returned to the old view of communication. I cannot agree with them on this point, for both comparative study and reconstruction of the mammalian lung show the contrary to be true.

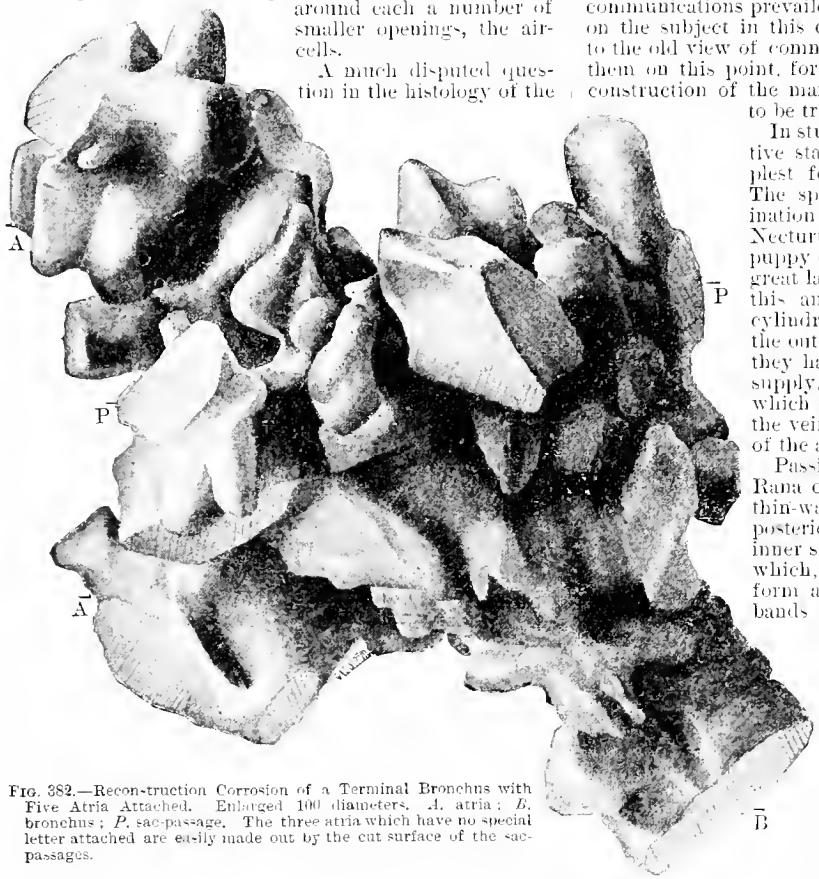

Fig. 382.—Reconstruction Corrosion of a Terminal Bronchus with Five Atria Attached. Enlarged 100 diameters. *A*, atria; *B*, bronchus; *P*, sac-passage. The three atria which have no special letter attached are easily made out by the cut surface of the sac-passages.

In studying the lung from a comparative standpoint, we find that the simplest form is found in the Proteida. The specimens I have used for examination have all been obtained from Necturus maculatus, the common mud-puppy of the Mississippi Valley and the great lakes of the West. The lungs in this animal consist of two elongated, cylindrical-shaped bodies, smooth on the outer and also on the inner surface; they have both an arterial and venous supply, the ultimate distribution of which is so arranged that the course of the vein is nearly at right angles to that of the artery.

Passing on now to Anura, we find in Rana catesbiana that the lungs are two thin-walled ellipsoid sacs, terminating posteriorly in bluntly-pointed ends. The inner surface is crossed by large bands, which, extending into the central cavity, form a coarse network; between these bands smaller bands are found which also form a network, thus giving the lung a honeycombed appearance. Between the lung of Necturus and that of Rana all grades of division of the inner surface may be found.

In Ophidia, the lung (for they possess only one, the right) is much elongated; the posterior two-thirds is perfectly smooth, externally and internally, but the anterior third of the inner surface becomes more and more subdivided, until we find in the anterior sixth that we have the inner surface divided into many small air-sacs, which communicate with the central cavity by a nearly circular opening. If we look down into one of these sacs with a low-power lens, 10–20 diameters, we shall see that each sac is divided into a number of shallow depressions, the air-cells. A careful examination of specimens prepared by cutting open previously blown-up and dried lungs, and sections of hardened specimens, failed to show any communication between neighboring air-sacs.

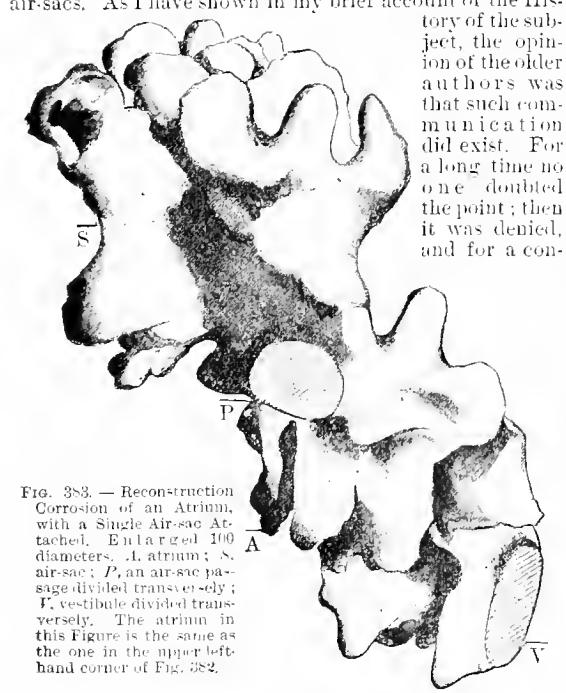

Fig. 383. — Reconstruction Corrosion of an Atrium, with a Single Air-sac Attached. Enlarged 100 diameters. *A*, atrium; *S*, air-sac; *P*, an air-sac passage divided transversely; *V*, vestibule divided transversely. The atrium in this Figure is the same as the one in the upper left-hand corner of Fig. 382.

Thus far the lungs we have examined have consisted of a large central cavity, having its wall either smooth or beset with larger or smaller cavities, which possess a more or less complex structure. The bronchus has entered the anterior end of the lung, but has not extended into its interior. There have been no partitions across the central cavity and extending the entire distance, dividing the lung into independent cavities. In Heloderma suspectum, one of

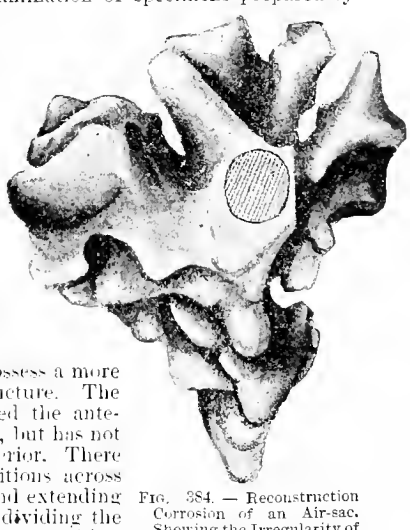

Fig. 384. — Reconstruction Corrosion of an Air-sac. Showing the Irregularity of Form. Enlarged about 50 diameters.

the Lacertilia, we find the central cavity divided by partitions which extend across the entire distance, dividing the lung into larger or smaller cavities, which are in their turn subdivided into smaller spaces, just as we saw in the frog's lung. The surfaces of these partitions are also covered with fine bands which divide them into small cells.

The bronchus enters the lung at the inner and upper sixth, and terminates in the partition which divides the posterior cavity from those in front of it. It occupies very nearly a central position. Lateral openings, more or less oval in shape, are found in the wall of the bronchus; these communicate with the different cavities. This opening is the only one which opens into any single cavity. Nowhere do we find an opening through the partition wall. The only medium of communication between one air-sac and another is that of the bronchus. The posterior sac which occupies the entire posterior third of the lung is much simpler in structure than those situated anterior to it. We shall find, as we continue the comparative study, that this posterior sac is slow to take on the complex structure found in those lying more anterior to it.

The lungs of the Chelonians show beautiful gradations in their division into cavities and in the complex subdivision of these cavities. In many forms the posterior sac is quite simple in structure, resembling the lungs of Necturus and of Rana; but we find the primary divisions extending deeper and deeper into the centre, until, in Macrochelys, we find that it has a similar structure to those lying anterior to it. The bronchus extends centrally to the posterior sac; the openings from the bronchus into the different sacs are nearly circular, and they are the only opening which each sac possesses. We found in Heloderma that there were no openings through the partition walls of the sac; the same is true of all Chelonians. The only means of communication between neighboring air-sacs is through the bronchus.

In Crocodilia the bronchus enters the lung near its centre and on its inner side; it passes somewhat obliquely into the lung, and at the junction of the lower and middle thirds breaks up into six to twelve tubular passages. The point where the bronchus breaks up forms a terminal bronchus; the tubular passages are elongated atria; opening out of them are numerous small air-sacs, which are subdivided into air-cells. There are no communications between one atrium and another, or between adjoining air-sacs. I have used in my study specimens obtained from the crocodile of the Nile, and from our representative of the group, the Florida alligator.

In Aves the type of the lung presents marked differences from that of reptiles on the one hand, and of mammals on the other. The lungs are closely attached to the ribs and their interspaces. The bronchus penetrates into the lung and breaks up into elongated tubular passages, which, in some instances, communicate with each other by means of short branches. These tubular passages are not true bronchi, because their structure shows a marked difference, and they do not give rise to terminal bronchi. They are to be considered as atria, and the alveoli, or true lung structure, arise from them just as we have found to be the case in the lung of the crocodile. By tracing the principal bronchi through the lungs we find that they communicate, by means of openings more or less circular in outline, with large air-bags situated in the abdominal cavity, or with air-spaces in the bones, etc. These air-bags must be considered as a portion of the lung, for they are directly continuous with the bronchi and are developed from them.[35] There are no communications between air-sacs.

The lungs of mammals I have studied by resorting to Born's[33] method of reconstruction.* In no instance have I found any communication between neighboring air-sacs or between one atrium and another. As was seen in the lungs of the lower animals, the only mode of communication was through the bronchus. I have examined carefully specimens taken from the lungs of man, the dog, the cat, and several other mammals, both in adult life, in the growing period, and in fœtal life, but have invariably failed to find any communication.

Blood-vessels.—We have to consider three vessels, the pulmonary artery, the pulmonary vein, and the bronchial artery. The relations of the pulmonary artery and vein before entering the lung can be found in all systematic works on anatomy. The position occupied by the bronchus, artery, and vein at the hilus of the lung has been already stated.

Within the lung the pulmonary artery follows closely the bronchi throughout their entire course. The divisions of the artery correspond to those of the bronchi; so if one knows the number of bronchi in a given lobe, the number of arteries is also known.

With the division of the bronchus into terminal bronchi and their breaking up into the parenchyma of the

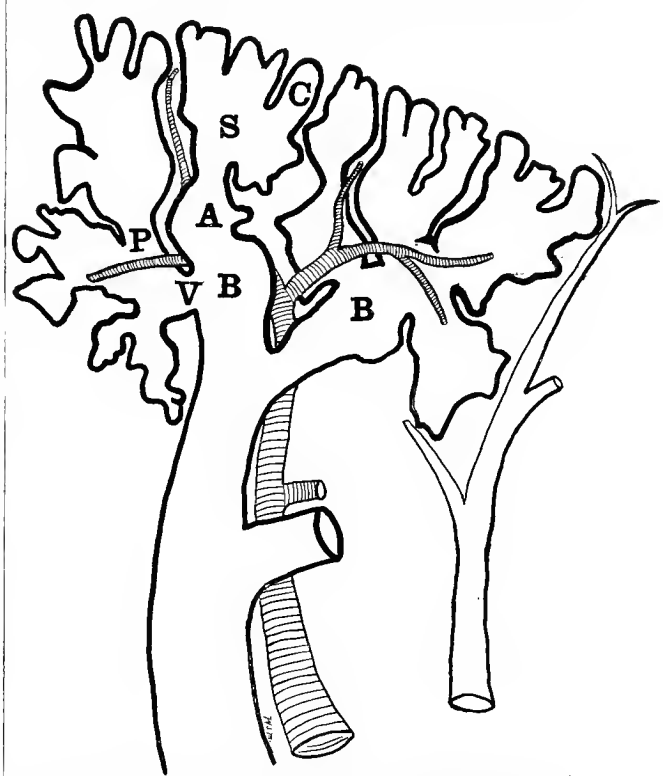

Fig. 385.—Scheme of the Lung Lobule. *B*, terminal bronchus; *A*, atrium; *S*, air-sac; *V*, vestibule; *P*, air-sac passage; *C*, air-cell. The shaded vessel is the artery, the vein is in outline.

lung, changes take place in the distribution of the artery; it penetrates into the centre of the lobule until it reaches a position beyond the terminal bronchus; there it breaks up into as many branches as there are atria, and from these branches are given off which pass to the air-sacs. There are also branches which correspond in size to those given off within the lobule, that arise from the artery just before entering the lobule, and supply the air-sacs which lie close to the terminal bronchus. As a rule, these air-sacs arise from an atrium which has taken a recurrent course.

On reaching the air-sac the artery divides into small radicles which run on the central side of the air-sac in the sulci between the air-cells, and finally are lost in the system of capillaries to which they give rise.

The capillaries anastomose with those of adjoining air-sacs, but the arteries do not anastomose with each other. There is, therefore, but a single system of capillaries in the wall of an air-sac or atrium. The capillaries have a

* Reconstruction methods have, so far as I have been able to learn, been made use of by Born, His, Selenka, Zimmerman, His, Jr., Piersol, Fol, and Mall in the study of embryos, and by Spelteholtz, Mall, and myself in histology.

diameter of about 7 μ, being slightly larger just beneath the pleura and somewhat smaller deeper in the lung. In length they are rather more than twice their diameter, and the space between the capillaries, the mesh, is a trifle more than the diameter of the vessel.

After the capillaries have formed from twenty to twenty-four loops they unite to form small venous radicles which are situated on the peripheral side of the air-sac. These radicles do not lie in the sulci between the air-cells, but run directly over their centre; they eventually form a small vein, several of which, uniting together, form the veins of the lobule. These larger veins run in the interlobular spaces and are situated as far away from the bronchus as possible.

We have therefore an artery on the central side of each air-sac, a vein on the peripheral, and between the two a rich capillary network, thus giving an arterial and venous side to each air-sac.

The bronchial arteries are distributed to the walls of the bronchi and run throughout their entire length; they are also distributed to the areolar tissue of the lung, the walls of the blood-vessels, and the lymphatics.

I have been unable to find any veins accompanying the artery. The bronchial artery forms a long-meshed capillary network that unites to form short veins which open into the pulmonary vein.

The question whether the bronchial artery opens into the pulmonary artery or vein, has been much discussed. I cannot here enter on a full description of my work on the subject, but will give the results.

The bronchial artery is distributed to the bronchus throughout its entire length, to the walls of the blood-vessels, the lymph-vessels, the connective-tissue sheaths and septa.

From the walls of the expanded end of the terminal bronchi two small vessels arise, which are formed by the capillary system, into which the bronchial artery breaks up; these pass out from opposite sides of the bronchus. Each vessel receives a small number of venous radicles from neighboring air-sacs, and in this way a short but quite large vein is formed which empties itself into the nearest pulmonary vein. As these two veins arise from the expanded end of the bronchus, they lie within the lobule, and form an exception to the rule that all veins lie on the periphery, while the arteries occupy the central portion of the lobule. In a few instances I have found small veins coming from the bronchus just before entering into the lobule; in other words, small veins may arise from the walls of the last forked division of the bronchus. They follow the same course as those within the lobule.

LUNGS, CROUPOUS AND OTHER INFLAMMATIONS OF. Consideration of this subject is here limited mainly to etiology in reference to the agency of microbes.

Weichselbaum (1887) holds that the bacteria found in the different forms of pneumonia are to be regarded as the cause of the inflammation, and taking cold as only a predisposing event. He considers the diplococcus as the most frequent cause.

Perret and Rodet (1887) have together made experiments of injecting microbes (presumably under the epithelial surface of the air-passages), and conclude that pneumonia may be produced by a variety, including those of typhoid fever, measles, scarlatina, etc.

Weichselbaum (1888) found bacteria constantly present in the different forms of pneumonia, and most active and abundant in early stages. In his opinion the virus is not a unity, but the croupous form itself may be due to several different organisms. The distinction of lobar and lobular, croupous and non-croupous, he believes to be anatomical merely—not etiological. Fränkel's diplococcus is the most common microbe found. Friedländer's being rare. This diplococcus (Fränkel's) is found in all the cavities about the nose; also in the brain, spinal cord, pleura, pericardium, interior mucosæ and submucous tissue. The same organisms are sometimes found in endocarditis and suppurative arthritis.

Monti (1888) withdrew the exudation of pneumonia from the lungs during life by means of Koch's syringe, and in twenty instances failed only once in obtaining micro-organisms. Fränkel's diplococcus was always found (Friedländer's never), sometimes associated with other micrococci. Inoculation of rabbits with the sputum always gave positive results, but produced pneumonia only when thrown into the trachea. Under the external skin it caused septicæmia; into the pleura, pleuritis and pericarditis, but never pneumonia; into the dura mater of a dog, after trephining, it caused meningitis.

Netter (1888) holds that pneumonia is transmissible through specific pathogenic micro-organisms, which multiply in the diseased foci, and leave the body chiefly in the sputa. The contagium resists desiccation and retains its activity for a long time outside the body.

The examination (1889) by Prudden and Northrup of seventeen children who died of diphtheria complicated with pneumonia, disclosed similar streptococci in both the diphtheritic membranes and the lungs of all but one of the cases. By using intra-tracheal injections of pure cultures of these streptococci, obtained from the lungs of the children, they uniformly produced lobular or broncho-pneumonia in rabbits.

Netter (1889) reports an infant born of a woman while ill of pneumonia. The child lived five days, and autopsy revealed pneumonia at the apex of the right lung, double pleurisy, suppurative pericarditis, and cerebro-spinal meningitis, associated with microscopic appearance of micrococci. It is presumed that the child was infected by the mother before birth; and similar observations have been made in rabbits, guinea-pigs, and mice.

According to Sternberg, Fränkel's diplococcus (called by him micrococcus Pasteuri) is widely distributed, and is often found in the sputum of healthy persons.

Mosler, of Greifswald (1890), gives a series of cases in one family. The father apparently contracted pneumonia outside and communicated it to the others. The

fluid from the lungs contained bacilli resembling those of septicæmia in the rabbit, but no micrococci of Fränkel nor of Friedländer.

Levy reports, in a Paris journal (1890), a case of congenital fibrinous pneumonia complicated with pleurisy and pericarditis. Sero-purulent fluid aspirated from the chest gave cultures of the diplococcus of Fränkel and Weichselbaum, and inoculations of the same proved their potency. The child was born thirty-six hours before the mother's death, and died, two days after birth, of broncho- and lobar fibrinous pneumonia combined. Fluid was drawn from the left ventricle of the heart and right lung, and cultures from the same gave Fränkel's diplococcus. This microbe was also found abundantly in the blood.

Platini (1890) found that inhalation of the pneumococcus failed to cause pneumonia, while the mucous surface of the respiratory tract maintained its integrity. After traumatism through the thoracic walls, or inhalation of ammonia or hydrochloric acid, infection took place. It was found that the animals after inoculation had more elevated temperature and more extensive pneumonic lesions, and succumbed more rapidly when subjected to refrigeration, than other animals similarly inoculated but not exposed to cold. On the other hand, exposure to cold without the inoculations failed to induce pneumonia.

Debove (1890) reports having found pneumococci in a case of meningitis complicated with peritonitis, but there was no pneumonia.

Netter observes that pneumococci are rare in peritonitis, but occur in most cases of meningitis. Cultures of pneumococcus have been made from the fluids of cerebral and spinal meningitis and encephalitis; also from those of pleurisy and empyema, both independently of pneumonia and complicating it.

Devoto, in many examinations of those dead from pneumonia, never found Fränkel's diplococcus in the kidneys. Luccatello generally found the blood free of them. But Canfield, at the pathological laboratory of Johns Hopkins Hospital, has found them in the blood and tissues of rabbits killed with Sternberg's sputa and with the prune-juice expectoration of pneumonia. Bozzolo reports the discovery of diplococci in the milk of a woman ill of pneumonia.

Several French physicians (Mosny, Laboullière, Strauss, and Brouardel) report fatal cases of pneumonia, in which they attribute the infection to the streptococcus of erysipelas solely. In like manner pneumonia coexisting with typhoid fever, scarlatina, small-pox, influenza, or dysentery, might be referred to the action of the microbes of one of these diseases on the lungs.

Assuming the correctness of the above observations, the following conclusions seem to be justified:

1. The most prevalent forms of pulmonary inflammation hitherto enumerated (croupous or lobar, and catarrhal or lobular) differ in degree and extent rather than in nature and cause.

2. Pulmonary inflammation is always accompanied by micro-organisms, and may be regarded as directly dependent on their action. The most common is the diplococcus of Fränkel, but several others are found operating singly or mixed.

3. The same micro-organisms affect other anatomical parts, producing inflammation in all instances. Various parts may suffer at the same time from the same kind of bacteria. Several species of bacteria may be found in the lungs at the same time, all concerned in the inflammatory process. Pneumonia, therefore, is not a specific disease, in the usual sense of the word *specific*.

4. A solution of continuity in the mucous surface of the respiratory tract is a necessary antecedent. Bronchial catarrh with cough is the most common predisposing cause; inhalation of an irritating vapor, gas, or dust, and violent injury of the pulmonary structure in any manner, are efficient causes also.

5. The common atmosphere near the ground habitually carries in suspension the necessary micro-organisms to excite inflammation in lungs susceptible to their action, and such susceptibility is most usual in the seasons of coughs and colds. One or more cases of pneumonia in a dense population, where colds and coughs are prevalent, may then light up an epidemic of this disease.

6. That condition of the respiratory tract which renders a person liable to pneumonia, probably exposes one to the infection of pulmonary consumption, wherever the bacillus tuberculosis may be present in atmospheric dust; and this accords with the frequent sequence of phthisis to pneumonia, the bacillus tuberculosis being slower in propagation and growth than most other disease germs.

As to treatment, intra-pulmonary injections of solutions of corrosive sublimate, potassium iodide, sodium benzoate, and iodoform have been tried, but the results have not been encouraging. Petresco claims extraordinary success from large doses of digitalis—the disease aborting in two or three days, and the physical signs disappearing altogether in three days. In some cases he avers that the subject has resumed work in twenty-four hours. A reasonable explanation is, the drug strengthens the heart's action and thus promotes the removal of the products of inflammation by the blood-current. Blisters over the chest may be supposed to increase the flow of blood through the parenchyma of the lungs, and so produce the same effect. In this view the earliest application is the most efficient, and such has been the experience of the present writer. *S. S. Herrick.*

LUXEUIL. This "almost unique" spa, situated in the Vosges region of France, has already been briefly referred to in Vol. IV. of the HANDBOOK. Owing to its importance, the following additional information may be found useful. The ancient town wears a picturesque aspect, and if the thermal establishment and casino are not so pretentious as are those of the more fashionable resorts, they are nevertheless supplied with all essentials for the cure of invalids. The chalybeate waters being freely "digestible," are taken with impunity by delicate women and even children. It is claimed that the surprisingly good results obtained in the treatment of anæmia at Luxeuil are due to the admixture of arsenic and manganese with the iron compounds. Of the eighteen springs found at this spa, fifteen are exploited. Bathing and drinking go hand in hand at this resort, few patients being subjected to only one kind of treatment. A so-called "crisis" is commonly produced by a course of Luxeuil waters. Mr. Wolff ("The Watering-places of the Vosges") describes this phenomenon as follows: "Even the saline waters produce this—a combination of all sorts of unpleasant sensations, describable and indescribable—insomnia, debility, palpitations, constipation (aggravation of constipation is a very usual first effect), cutaneous eruption, sometimes, and in acute cases even fever. When the water taken is the chalybeate, the 'crisis' appears in an aggravated form. However, all this does not last very long, and the doctors rather like to see it, on the principle that it shows the waters to be doing good. Sometimes, however, there is a recurrence of the same symptoms in the third or fourth week. Whenever that happens it is held to show that the treatment has been carried far enough and should be discontinued. On its cessation the unpleasant symptoms subside almost at once, and give place to an improvement which in some cases is described as really astonishing."

The same author also states that "the marked difference in the Luxeuil waters is attributed to the difference in the triassic strata from which they spring. There are, first, the rather warm springs, ranging from 95° to 132° F., which are alkaline and saline, but of rather slight mineralization, the total of solid matter in the litre not exceeding 1.17 gramme. These resemble, generally speaking, the Plombières waters, and are of course considered useful for much the same classes of cases—rheumatism, liver complaints, dyspepsia, diabetes, affections of the respiratory organs, and some female maladies. They share with the waters of Plombières the peculiarity that, however hot they be, flowers (or other vegetable matter) thrown into them do not at once shrivel up and fade, but rather assume at first a brighter coloring. Secondly, there are the chalybeate waters,

which are less warm, indicating from 72° to 86° F., even less mineralized—having but 0.9 gramme of solids in the litre—but remarkable for holding their iron in combination with a strong dose of manganese. (This really applies to the saline waters as well, only the quantity of iron is much smaller). The chalybeate waters, as might be expected, contain a very much larger proportion of free carbonic acid—it is said about six times the quantity. In both varieties of waters there occurs a fair amount of nitrogen, and some arsenic. It is the ferruginous water which makes Luxeuil almost unique, and so wonderfully effective in women's and children's anæmia, hypochondria, the *malaria urbana*, rheumatism—articular, muscular, or fibrous, more particularly rheumatism in the intestines,—neuralgia, uterine complaints, anæmia (*prétendue*), palpitations, scrofula, etc. The water is held to be contra-indicated only where anæmia arises from organic degeneration."

Analysis.—The subjoined table gives a fair average of the different springs. In one thousand parts there are contained :

Sources Thermales.	Parts.	Sources Hyperthermales.	Parts.
Silica	0.0360	Silica	0.0988
Phosphate of iron	0.0037	Carbonate of lime	0.0732
Carbonate of iron	0.1093	Carbonate of magnesia	0.0075
Carbonate of manganese	0.1074	Carbonate of maganese	0.0023
Carbonate of magnesia	0.0136	Carbonate of iron	0.0036
Carbonate of lime	0.0810	Sulphate of soda	0.1646
Chloride of sodium	0.0369	Chloride of sodium	0.7512
Chloride of potassium	0.0240	Chloride of potassium	0.0585
Chloride of magnesium	0.0240	Chloride of lithium	0.0096
Chloride of calcium	0.0296	Carbonate of soda	0.0216
Salts of arsenic	traces	Arseniate of soda	0.0006
Organic matter and loss	0.4469	Boracic acid, fluorine	traces
		Organic matter and loss	0.0757
Total of solids	0.9005	Total of solids	1.1684
Temperature 70° to 86° Fahrenheit.		Temperature 95° to 133° Fahrenheit.	

Accommodation.—The hotels and boarding-houses of Luxeuil are not in all respects first-class. Nevertheless most patients can be made tolerably comfortable for the few weeks time which the "cure" calls for. The people of the place are very obliging to foreigners.

Edmund C. Wendt.

LYSOL. This is a proprietary preparation of cresol introduced to supersede creolin, the best known solution of this valuable disinfectant. Since the discovery of the active antiseptic properties of cresol various methods have been adopted to secure a solution suitable for practical purposes, and numerous patented preparations have been supplied to the profession. Many disadvantages attend these solutions, the most common being a precipitation of the constituents when added to water, which produces turbid mixtures, and an annoying soapiness that renders the instruments and the hands of the operator slippery and unpleasant. The advantages claimed for lysol over the other cresol compounds are that it forms a clear solution when mixed with water, contains a greater amount of cresol, and is perfectly free from injurious qualities. It is said to be prepared by dissolving the cresols, which distil between 190° C. and 200° C., in fatty matter and subsequently saponifying by the addition of alcohol. It is a brown, oily-looking, clear liquid, with a feeble, aromatic, creasote-like odor. It is said to contain fifty per cent. of cresol. Its solution forms a soapy, frothing fluid, which only becomes turbid when mixed with hard water, the extent depending upon the quantity of lime-salt present; this turbidity increases upon standing for some time. Lysol mixes freely with alcohol, glycerine, chloroform, and benzene. The saponaceous character is claimed as an advantage, as it facilitates cleansing and disinfecting the site of the operation and the hands of the operator. It acts in a manner equal to the best soap, and readily removes all dirt, fat, and resinous matter. In order to avoid the annoyance of the soapy instruments and to facilitate the tying of sutures, the hands and instruments may be rinsed in sterilized water to remove the lysol solution.

The disinfectant and deodorizing properties are undoubted. They are such as would be expected from a solution of cresol of such a strength, and experiments have shown that a 0.3 per cent. solution is capable of arresting the growth of the staphylococcus pyogenes aureus. It is also perfectly harmless and devoid of any toxic action.

For surgical purposes it is used in different degrees of strength. For disinfecting the hands and cleansing the body of the patient a five per cent. solution is used by rubbing into the parts thoroughly, and then washing it off in a solution of one or two per cent. For disinfecting instruments and for irrigation during an operation a one or two per cent. solution is prepared, and for gynæcological and obstetrical purposes a solution of one-half per cent. is sufficient.

Lysol is indicated and may be used in all forms of inflamed and ulcerated surfaces in which a disinfectant is required. On mucous surfaces, when used in stronger solution than two per cent., it causes a burning and painful sensation which lasts for some time, but otherwise is perfectly unirritating.

Lysol has recently been administered internally (*Therapeutic Gazette*, November, 1892), in the treatment of scarlet fever. In doses of three to ten drops, of a mixture of lysol one part to two parts of sherry wine, three times a day, the temperature of the patient was rapidly lowered, the albumin disappeared from the urine, and the general condition of the patient improved. In dysentery and choleraic diarrhœa it was serviceable when used as a clyster in the strength of a one per cent. solution. From the satisfactory results thus obtained it is suggested as a remedy in Asiatic cholera, by giving immediately 2.5 grammes of lysol mixed with a stimulant, and thoroughly washing out the intestines with a one per cent. solution. *Beaumont Small.*

MAGNETO-THERAPY. Magnetism is known to be a remarkable force, and it is not strange that from time to time the occult power of magnets has been brought to bear upon certain disorders by physicians in the hope, and often with the belief, that it would be efficient as a remedial agent. We need not seek far in medical literature for matter relating to magneto-therapy. For instance, Roberts Bartholow, in the third edition of his work on "Medical Electricity," published in 1887, says: "We know that a current circulates in a magnet. If a powerful magnet is brought near to the skin, opposite electricities are attracted to the poles and currents are induced. About the point of application, therefore, the skin will be acted on directly by the magnetic current and by an induced current. The production of physiological effects, which can be recognized, is therefore merely a question of magnetic strength." He then quotes Dr. Vansant, as assuming the body to be diamagnetic: "By applying north and south polarity to different parts, very extensive subjective impressions are experienced; they are of two classes of heightened organic activity and the opposite condition."

He then adds: "That impressions of a very decided kind are produced by the application of strong magnets is evident in the experience of Dr. Proust and Dr. Ballet, who continued a course of investigation begun by Charcot at Salpêtrière." They ascertained that magnets could not be applied with impunity, for, if applications were prolonged, pains were felt in the epigastrium and thorax, making respiration painful, digestion was disordered, and boulimia brought on. These results were so uniform that there seemed to be no doubt of their genuineness in the minds of the investigators.

Under the heading "Therapeutical Application of Magnets," Dr. Bartholow quotes Dr. Hammond as preferring a horseshoe magnet, and advising that several of the same size be kept, so that by clamping them together more power can be obtained. The author adds: "Hammond insists on the necessity for the application of both poles in many cases, and therefore uses the horseshoe magnet."

"Hammond has used magnets in nine cases of chorea, in two 'complete cures being produced in a few minutes.'"

"In two cases of hemiplegia with hemianæsthesia Hammond had very surprising results from the application of horseshoe magnets, the sensibility returning immediately, and in one the hemiplegia was recovered from in a few hours."

Professor Benedikt, of Vienna, who has made much use of the magnet in nervous affections, has taught that erethitic forms of hysteria are better treated by the magnet than by electricity, hydrotherapy, or drugs. A magnet being applied to the sensitive vertebræ, without removal of the dress, the irritable patient soon becomes quiet and even quasi-paralyzed. The magnet, therefore, "increases the resistance to conduction in the motor nerves." The muscles gradually relax, the respiration becomes sighing, consciousness slowly disappears; the resistance to conduction in motor nerves "could easily become absolute." The two poles have different effects. Sometimes one pole to a hyperæsthetic ovary fails to relieve pain, whereas a change of the poles causes its speedy disappearance. According to him the magnet must be employed with due caution, since patients may be injured by it.

Of late years Luys has in Paris brought to the attention of the profession some of the marvellous effects of magnets upon the human body, but it is plain that Luys has been carried away by his own imagination as well as by the imposition and simulation of his patients. Where not directly due to feigning, the facts in his experiments can readily be explained by the phenomena of suggestion.

The magnets made use of by physicians are generally those of a horseshoe shape, varying in length from a few inches to a foot. They are the so-called permanent magnets.

They exert a traction force equivalent to several ounces and in some instances to as much as three or four pounds. But electro-magnets may be made infinitely more powerful. Some may sustain two hundred pounds to each square inch, or fourteen kilogrammes to the square centimetre of active surface on either pole, that is to say, twenty-eight kilogrammes to the square of active surface on either pole if both poles are alike and share the load.

A propos of the effects of the magnet upon the human body, some experiments were recently made by Dr. Frederick Peterson and Mr. A. E. Kennelly, at the Edison Laboratory at Orange, N. J. ("Some Physiological Experiments with Magnets at the Edison Laboratory," New York *Medical Journal*, December 31, 1892). Several of the largest magnets known to modern science were made use of by the experimenters. In one of them the intensity of the magnetic field between the poles was about five thousand centimetre-gramme-second lines to the square centimetre, a field twenty-seven thousand seven hundred and seventy-eight times that of the earth's horizontal component that aligns the compass needle. A microscope was properly arranged so that substances might be examined when exposed to the operation of this force. Iron by hydrogen, dry or placed in water, was observed to act as do iron-filings when similarly treated.

Dry powdered hæmoglobin exposed to this magnetic field was not visibly affected by it.

Human and frog blood-corpuscles similarly examined showed not the feeblest traces of polarization, movement, or vibration.

Living ciliated epithelium from the pharynx of a frog was absolutely unaffected by the magnet as it was magnetized and demagnetized by the making and breaking of a one hundred and twenty volt current in the huge coils. The delicate ciliary movement continued without change of any kind.

The circulation of the blood in the web of the foot of a curarized frog was observed under the microscope in the same way, and it was demonstrated that the magnet had not the faintest influence upon the blood or its movement.

A small dog was placed in the cylinder of a set of idle field magnets and kept for five hours exposed to a magnetic field with an intensity of 1,000 to 2,000 c.g.s.* lines to the square centimetre, and not the slightest visible effect was produced upon the animal.

The next experiments were directed to studying the influence of magnetic fields on the human brain. The machine employed for the purpose converts about 70 horse-power at full load. The armature and one journal were removed, leaving the space between the pole-pieces free. This cavity is 35 ctm. (fourteen inches) in diameter and 60 ctm. deep. The weight of this electro-magnet is over five thousand pounds, and the intensity of the magnetic field produced within the polar cavity after removal of the armature, though not uniform, may be estimated at a mean of 2,500 c.g.s. lines to the square centimetre. A long board was placed upon the base plate leading into this polar cavity, and the subject experimented upon lay on his back upon the board with his head and shoulders in the cavity between the poles, and exposed thus to the full influence of the magnetic field. There would be comparatively feeble residual magnetism with no current in the coils. A switch so nearly silent in action as to be inaudible to the subject was arranged to close and open the exciting current circuit through the field coils. On closing the switch nearly the full magnetic intensity would be active and permeate the head within one second, and on opening the switch the whole intensity would disappear in one second.

Five men, the authors being among the number, were subjected to trial, and the following description of one case serves for all, since the results were precisely the same:

The subject lay back upon the board and concentrated his attention upon his sensations. His right wrist was extended and was grasped by one observer, who took sphygmographic tracings of the pulse. A second observer placed a hand on his chest to observe any irregularity that might occur in respiration. A third observer, in view of these two, but unseen by the subject of the experiment, opened and closed the switch that excited and relaxed the field, signalling to the first two observers as he did so. The strong magnetic influence was therefore turned on or off at will and without the knowledge of the subject. Several sphygmographic tracings were taken in each of our subjects, and in one the knee-jerk was tested continuously.

The sphygmographic tracings taken continuously during the *séance* show no change in regularity, in spite of the making and breaking of the enormous magnetic influence during its registration. The respirations were not changed in the least. The knee-jerk also presented absolutely no change. As to common sensations, there were none that could be attributed to the magnetic influence, and the subject could not discover when or whether the field had been excited. The testimony of all five subjects was alike. In one experiment the subject held a steel screw in his mouth, and was then able to tell when the poles were magnetized or demagnetized, but only by the pulling of the screw to one side or another, not by any peculiar sensation or taste.

Experiments were then made with reversed magnetism. A huge coil of stout, cotton-covered copper wire, about 30 ctm. high and 25 ctm. internal diameter, weighing 70 kilogrammes and composed of nearly 2,000 turns, was so arranged that the head of the subject could be freely introduced within the coil. Its resistance was 10 ohms, and an alternating current of 1,200 volts, making 280 alternations per second, was passed through this coil. The magnetic field would thus be reversed 280 times per second. Each of the authors acted as subject in this experiment. No appreciable effect of any kind was produced when the head was introduced.

The authors concluded that the most powerful magnets known at the present time have no effect whatever upon the organism, neither upon the iron of the blood, upon the circulation, upon ciliary or protoplastic movements, upon the sensory or motor nerves, nor upon the brain.

* c.g.s. = centimetre, gramme, second.

The ordinary magnets used in medicine by Hammond, Benedikt, Charcot, Luys, and others have a purely suggestive or psychic effect and would be quite as useful if made of wood. *Frederick Peterson.*

MALFORMATIONS, PRODUCTION OF. Among the invaluable services of embryology in adding to the general fund of biological knowledge none have been more signal than the removal of developmental anomalies from the domain of fanciful speculation and the establishment of a rational teratology based upon the laws of development. Not only has embryology indicated the lines along which the production of anomalous development progresses, but, likewise, it has indicated the broader morphological significance which in many cases exists, emphasizing especially the fact that not infrequently deviations in the higher types correspond to the normal and usual condition of lower forms.

Notwithstanding the advances in the comprehension of the true significance of variations which the progress and increased accuracy of our knowledge of the course of normal development have rendered possible, there are still numerous deficiencies in our understanding of the primary causes producing malformations—breaks which renewed investigations and further observations alone can supply. The most rational teratological classification, it is evident, would be that in which malformations were grouped according to the various methods of their production; unfortunately, however, with the present limitations and uncertainty of our knowledge of these processes all attempts at such grouping must be imperfect and provisional.

Defects arising from the mechanical effects induced by diseased and unusual conditions of the fœtus, as accumulations of fluid in abnormal quantity within the body-cavities or the undue size of organs, which may, in an adverse manner, directly influence the development of surrounding parts, must be distinguished from those distortions resulting from inflammatory processes, these latter falling under the category of pathological changes rather than of developmental deviations.

A few words concerning the much-vexed question as to the responsibility of maternal impressions in the production of malformations may here, at the beginning of the consideration of our subject, find place. While fully appreciating the sincere convictions of not a few in the belief of the sufficiency of such impressions, and in the sometimes apparently convincing testimony adduced in support of such views, the writer must confess his inability to attach much importance to these influences. In this connection attention must once more be called to the significant fact that in the majority of cases the affected parts are already well advanced in their development before the supposed impression takes place; in fact, not infrequently the developmental deviations necessary in the production of the malformation attributed to the maternal impression take place before the existence of pregnancy is even suspected. While it may be conceived that certain defects may result from nutritive changes induced as the consequence of profound nervous impressions on the mother, yet to those familiar with the embryological significance of malformations the basis of the popular belief in the potency of maternal impressions will appear as depending more upon the very natural disposition to find an explanation for otherwise uniutelligible misfortunes in coincidental circumstances, rather than upon well-established or accurately observed phenomena.

The various headings here introduced make no pretence to systematic arrangement, but are simply provisional, as affording convenient groups for the consideration of nearly-related forms of deviation. Bearing these limitations in mind, malformations may be classed, with regard to their mode of production, into:

I. Those produced by variations in nutrition and growth—either excessive or arrested.

II. Those produced by defective union of component embryonic parts.

III. Those produced by cleavage—either partial or complete—of the primary embryonic cell-mass.

I. *Malformations produced by variations of growth.*

a. The manifestations of *excessive* growth may be present in all parts, resulting in a general increase of the entire organism, or they may be limited to some particular region, as half of the body, a simple extremity, or a special finger or toe. While slight deviations from the normal average length (50.5 ctm. or about twenty inches) and weight (3,250 grammes, or about 7.2 pounds) of the newborn infant constantly occur, yet well substantiated instances where these figures are exceeded to any marked extent are by no means frequent. A height of over 200 ctm. may properly be considered as gigantic.

It is worthy of note that individuals conspicuous by reason of their extraordinary proportions quite usually were children of ordinary size, whose parents, likewise, were of average stature. The case reported by Beach[1] is a striking exception, since the father measured seven feet seven inches, and the mother seven feet nine inches. Their first child, immediately after birth, was twenty-four inches long and weighed eighteen pounds, while the second measured thirty inches and weighed twenty-three and three-fourths pounds. The assumption of an excessive amount of formative material, in the attempt to find an explanation of these instances of unusual growth, must be unsatisfactory when it is remembered that in some cases almost ten years have elapsed before the child evinced any disposition to excessive size. It must be admitted that our knowledge extends little beyond surmise as to the cause of these cases.

Equally uncertain are the causes leading to the curious excessive growth limited to some particular part of the body, as when one extremity, a hand, or even a single finger, attains inordinate dimensions without participation of the adjacent parts. It is evident that such instances of excessive growth must be carefully distinguished from enlargement the result of inflammatory processes or other pathological conditions. As with the instances of general increase, so here, also, the affected parts may for some time after birth present no unusual characteristic, the tendency to extraordinary growth first becoming noticeable at a later day. The subcutaneous connective tissues share with the osseous, vascular, and lymphatic tissues in the participation of the changes in question.

b. Variations due to *defective* growth may be grouped into: 1, those in which a general decrease in size is accompanied by uninterrupted development; 2, those in which the diminution is dependent upon arrested or anomalous development.

The first group is represented by true dwarfs, in which physical development has taken place to completion although the resulting organism is of unusually small dimensions, owing to insufficient growth. Individuals greatly reduced in size, and, at the same time, completely developed, are of rare occurrence; concerning their etiology nothing is known. True dwarfs are, of course, to be carefully distinguished from the not infrequent cases where the diminished size depends upon the effect of pathological processes, as caries or inherited constitutional vices. Heredity plays as unimportant a rôle in the production of dwarfs as in that of giants, since, generally, the parents are of normal size; and, further, not infrequently the dwarfs during early infancy differ but slightly, if at all, from other children of similar age, the diminutive size, which later renders them conspicuous, attracting attention only as age advances.

The second group, including those diminutions dependent upon arrested development and subsequent atrophy, embraces malformations varying greatly in degree, from a rudimentary finger to a shapeless acardiacus. The impaired nutrition, to which the production of these malformations is due, may be the expression of general causes affecting the development of the entire organism and resulting in general atrophy, or of but local causes exerting their unfavorable influence within a very limited area; in these latter cases they may be mechanically induced as the result of undue pressure, either from without or from within the embryo. The investigations of Kollmann[2] and His[3] render it highly probable that general malnu-

trition of the embryo in its earliest stages, resulting in the production of the "abortive" forms, to which the last-named author has recently again called attention,[4] is much more frequent than is generally supposed. These abortive embryos, which may be either nodular, cylindrical, or contorted in outward form, may remain stationary in their development within their membranes for weeks or even months without decomposition or absorption. This fact affords the explanation for the not unusual, apparently irreconcilably small size of the product of conception and the length of time during which pregnancy has existed. These stunted embryos are often the seat of a peculiar proliferation of wandering cells, which invade the entire organism and obscure its histological details.

The group of "acardiac" monsters, likewise, furnishes conspicuous examples of interrupted development brought about by impaired general nutrition. In such cases an atrophic fœtus frequently is associated with a well-developed, and possibly entirely normal, mate, a common placenta, with double cords, being generally shared by the two.

Regarding the manner in which these malformations are produced opinions are by no means in accord. The older view of Claudius[5] attributes the atrophic changes primarily to the reversal and impairment of the circulation, brought about by the overpowering vigor of the stronger fœtus. This doctrine has been warmly defended and further elaborated by Ahlfeld,[6] according to whom the production of an acardiac monster is largely accidental.

The development of an ovum containing two embryonic areas ordinarily results in the formation of "homologous" twins, in which great physical similarity is very pronounced. In any event the development progresses with regularity until the formation of the allantois at about the twelfth to thirteenth day; if the growth of this organ proceeds with equal pace in both embryos the available space for attachment offered by the false amnion will be equally shared, and both embryos will be provided with allantoic, and later placental, circulations fully sufficient for their nutrition. The slight communication between the circulations, established by the anastomosis of the allantoic capillaries, which is usually found in such homologous twins, exerts no untoward influence on either embryo, both being born, at the close of gestation, fully capable of maintaining post-embryonic life.

When, on the other hand, the connection between the two circulations involves large vessels, unequal propelling forces in the two embryos may lead to the gradual suppression of the normal blood-current of the weaker fœtus, resulting in its death, followed by the subsequent disappearance of the amniotic fluid and cavity, and the pressing of the unfortunate fœtus against the uterine walls, where, by the continuous pressure exerted by the increasing bulk of the stronger surviving fœtus, the dead product is reduced to the thickness of stout parchment, producing an atrophic mass to which the term *fœtus papyraceus* is sometimes applied. In those cases where the allantois grows with unequal rapidity in the two embryos the fate of the weaker embryo is somewhat different. The allantois of the more vigorous attaches itself to the partial or complete exclusion of the less fortunate embryo, the latter being thus compelled to seek attachment for its allantois in the remaining unappropriated part of the area destined to form the placental attachment or chorion frondosum.

Where, however, all of the placental area is already secured by the allantois of the first embryo, a secondary attachment to the united allantois of the first embryo is all that remains for the second fœtus to secure. Embracing this last source of nutrition, the weaker fœtus forms anastomoses with the allantoic or placental circulation of the stronger, and thus becomes directly dependent for its nutrition upon the circulation of the latter, constituting an *allantoic parasite* (Ahlfeld).

Owing to this dependence, according to the views of the followers of Claudius, a reversal of the blood-current within the vessels of the weaker fœtus takes place, and is the prime factor in the production of omphalositic monsters, with the accompanying imperfections in many organs. The heart, naturally, is greatly affected by the changed conditions of circulation, becoming, in numerous instances, reduced in function to constitute but a part of the vascular channel. The atrophy and frequent disappearance of the heart was formerly regarded as an almost constant characteristic of these malformations, as expressed by the commonly applied term "acardiac;" that such condition, however, need not necessarily be present has been pointed out by Ahlfeld, who has collected fourteen cases where "acardiac" monsters possessed more or less developed hearts. The young organ may adapt itself to the reversed blood-current to an extent sufficient to enable it to take part in the propulsion of the stream. The quite usual relatively much better developed condition of the posterior, lower, or caudal half of the fœtus, is generally attributed by the supporters of Claudius to the more favorable situation of these parts to secure nutrition sufficing for at least partial development, while the upper portions of the fœtus are denied nutrition adequate to prevent the atrophy and disappearance so commonly observed. That sometimes, however, the reverse may occur is shown in the case recorded by G. W. Koch,[7] in which the neck, trunk, and upper extremities were well developed without even a trace of a heart being present. In those instances where the available blood-supply is insufficient for the nutrition of even the lower part of the fœtus the entire organism becomes converted into a shapeless mass, retaining but little resemblance to the human form, and representing the so-called *amorphous acardiac* monsters.

Opposed to the foregoing views, ably supported by Ahlfeld, are those of Dareste,[8] Panum,[9] Perls,[10] Breus,[11] Koch, and others, who maintain that the reversed blood-current and accompanying changes are secondary and dependent upon an inherent primary defect in the embryo of so grave a nature that development beyond a certain stage becomes impossible. The destruction, which otherwise would be the inevitable fate of such embryo, is partially averted by the opportune assistance derived from the anastomosis of its allantoic circulation with that of its more fortunate companion, from whose more vigorous circulation a donation is received capable of maintaining the partial nutrition of a larger or smaller portion of the affected embryo.

The view advanced by Cleland[12] as to the origin of acephalic and other lowly developed types of monstrosities corresponding to the acardiaci, opposes that of Claudius, and refers the origin of these forms to changes which follow primary posterior or "abcaudal" fission. According to this author, in the cases in question, one of the two segments resulting from such division develops with less vigor than the other, and, in consequence of the unequal growth of the segments and their external allantoic attachments, becomes subjected to greater and greater stretching, until finally separation takes place. One part of the weaker embryo remains attached to, and often within the stronger, while the other portion becomes free, and, where the allantoic circulation is established, capable of maintaining an imperfect existence, resulting in the well-known types of acardiac monsters. Should the weaker embryonic segment fail to form external attachments, it remains connected with the more robust mate, and probably becomes one of the more or less pronounced parasitic forms of double monsters.

Whatever be accepted as the detail of the immediate process by which these highly aborted forms of malformation are produced, it seems certain that their origin depends on a primary impairment of vitality of one of the embryos, as the result of which tardiness in securing adequate allantoic attachments, and failure in maintaining a successful and independent circulation follow. Weighed by the standard of our present knowledge, the changes observed in the circulation of such malformations can no longer be regarded as of the same primary significance as claimed for them by Claudius and his supporters, but rather as secondary phenomena, depending upon more deeply lying fundamental causes.

In seeking the interpretation of those examples of arrested development and incomplete differentiation af-

fecting the lower extremities in various degrees, from the suppression of a single digit to the rudimentary development and fusion of both lower limbs, as in *sirenomelus*, it is difficult to determine to what extent such developmental arrest depends upon external mechanical influences as contrasted with deficiencies of formative material and force.

Perls, Dareste, Gebhard,[13] and others concur in ascribing to an abnormally narrow amnion the principal rôle in the production of such arrests of development. Admitting, as we must, that important modifications may undoubtedly be referred to the direct limitations of the enveloping membranes, yet the symmetry frequently observed in the defects under consideration, together with the fact that sometimes, as in phocomelus, those parts most directly and continuously exposed to external pressure are much better developed than those which are more deeply placed and less exposed, strongly emphasizes the inadequacy of referring to merely mechanical influences the production of such anomalies, and renders imperative the assumption of the presence of a much more deeply seated cause of the arrest of development encountered.

II. *Malformations produced by the defective union of component embryonic parts.*

The limits of the second group of malformations, depending upon the imperfect union or fusion of parts originally distinct but normally uniting in the course of development, are very wide, and include an extended series of defects, which vary in their significance from slight inconvenience, as simple harelip, to great deficiencies incompatible with life, as extensive spina bifida.

These defects naturally fall under two heads: *a*, those arising from imperfect union of embryonal parts, originally separated; *b*, those resulting from incomplete closure of fœtal passages.

In connection with the anomalies embraced within the first sub-group, the early embryonic relations and processes must be recalled, especially the fact that the embryo largely develops by the fusion of two symmetrical halves. These halves, at first lateral tracts, differentiate into two sets of folds—dorsal and ventral. The former unite above the embryonic axis, as defined by the notochord, to form a dorsal tube, the neural canal; the ventral folds join below the axis to form an imperfectly defined primitive digestive tube, whose ventral wall, throughout a variable distance, is incomplete for a time, opening directly into the umbilical vesicle or its duct, the last trace of this connection usually disappearing only at birth. The lateral parts of the dorsal or neural folds are continued into the marked duplications forming the amniotic folds, which gradually cover in, at first the dorsal, later, the ventral surface of the embryo. By the elongation ventrally of the root of the primary amniotic folds, the tissues embraced within the latter (the ectoderm and the parietal layer of the mesoderm) gradually encompass the primitive digestive tube and form the ventral body-walls, the umbilicus marking the position where the last communications between the cavities of the fœtus and external structures exist; likewise, at the umbilicus, the embryonic parietes and the amnion are continuous.

On comparing the normal union of the dorsal and ventral folds it will be seen that while the dorsal line of fusion is unbroken the ventral line of closure is incomplete, being interrupted by the mouth and umbilicus primarily, and by the genito-urinary and anal openings secondarily. As is to be anticipated from these relations, malformations due to defective union along the anterior or ventral line of closure exceed in frequency those of the posterior or dorsal surface.

Without entering into a detailed account of the mode of production of the numerous defects included within the first of the above sub-groups, a brief consideration of the most important of such defects may claim attention.

The region of the face and neck is a favorite seat of such imperfect unions, a tendency readily appreciated when we recall the manner in which these parts are so largely derived from the tissue supplied by the visceral arches, together with the adjoining portions of the head. The most frequently observed defect of this group, the lateral labial cleft or harelip, results from the faulty union of the central naso-frontal, or intermaxillary, process with the superior maxillary or upper division of the first visceral arch. Harelip may be uni- or bi-lateral, and may be associated with defective development of the adjacent bony structures, as maxillary and palatal cleavage. When unilateral, harelip is more frequently limited to the left side, in explanation of which the tendency of the embryo to lie upon the left side in its early stages has been assumed to predispose to the formation of disturbing amniotic folds. Conspicuous anomalies are produced when the intermaxillary process fails to develop, the space between the ends of the superior maxillary processes appearing as a wide central labial cleft. Open naso-lachrymal ducts and oblique facial clefts are other forms depending upon defective union of the margins of corresponding embryonic furrows, while fissures of the cheeks, clefts, fistulæ, and cysts of the lower lip and defective inferior maxilla are further instances of imperfect fusion, or of insufficient formative material. The visceral furrows, as is to be anticipated, offer a productive field for defects of this class, as illustrated in the deviations about the external ear resulting from the imperfect development of the first outer visceral furrow and its secondary tubercles. Persistence of the lower visceral furrows gives rise to the laterally situated cervical fistula, those occupying the median plane resulting from the imperfect fusion of the visceral arches at their inner ends. The question as to the existence of a delicate epithelial partition separating the external furrow from the corresponding inner pharyngeal pouch is still a subject of non-agreement. A number of authors agree with His[14] in denying the existence of a free communication between the outer and inner furrows, unless artifically produced, while many others hold that secondary rupture of the epithelial partition takes place spontaneously and without violence after a variable length of time. Notwithstanding the retention of the epithelial septum during embryonic life, which condition the writer must continue to regard as the usual one before birth, there seems to be no reason why this delicate partition may not disappear subsequently, especially when viewed in the evidence of such cases as those recorded by Sutton[15, 16].

The production of a complete median cervical fistula has been attributed by Marshall[17] to the persistence of a rudiment of the median portion of the thyroid body, the thyro-glossal duct, which enlarges and subsequently opens on the free cutaneous surface. As opposed to this view, Kostanecki and Mielecki[18], Kanthack[19, 20], and others refer the fistula in question to a breaking through of the pharyngeal pouches into the still present remains of the *sinus cervicalis*. Diverticula and cysts also arise within the pharyngeal walls as vestiges of the visceral pouches.

Imperfect approximation and fusion of the parietal plates, to which the ventral body-wall owes its origin, results in defects varying from slight sternal clefts to gaps involving the entire line of ventral union. The causes leading to these defects are various and by no means free from complexity; in addition to the more mechanical influences opposing the normal union, as the disturbing presence of intruding amniotic folds or of the unusual interposition of excessively enlarged, displaced, or abnormally adherent viscera, the effects of insufficiency or distortion of formative material, together with developmental inertia, must likewise be recognized as active factors in causing the arrested unions.

Excessive size of the heart is frequently the cause of imperfect closure of the thoracic walls, cardiac ectopia being sometimes associated with these defects. Likewise abnormal adhesions may limit the development of the ribs, forming lateral clefts through which a pulmonary hernia may appear. The same influences which prevent the perfect union of the anterior thoracic walls may affect the diaphragm to the extent of permitting the formation of diaphragmatic hernia, which may include the migration of a large part of the intestinal tract.

While the thoracic clefts not infrequently are prolonged into the upper portion of the abdomen, it is in the lower or caudad part of the line of ventral union that the defects of closure occur with greatest readiness, a tendency finding its stimulus in the passage through the body-wall, at the umbilicus, of the several structures connecting the fœtus with its external attachments. The normal conditions thus favoring incomplete union, the supervention of causes retarding closure, as amniotic adhesions or excessive bulk or abnormal position of the abdominal viscera, may readily prevent the approximation of the abdominal walls and produce permanent fissures through which more or less extensive extrusion of the viscera may take place.

Such imperfections of slight degree, involving only the umbilical ring, are of frequent occurrence; especially related to the patulous condition of the umbilical ring are the protrusions of the gut, either as the result of abnormal retention within the cord of that part of the intestine which, until the tenth week of fœtal life, lies without the abdominal cavity, but subsequently is drawn within, or, more seldom, as the result of later secondary protrusion of the gut through the still open ring. A familiar example of the persistence of these fœtal relations, to a slight and imperfect degree, is presented in the occurrence of Meckel's diverticula, where the retention of the lumen of the proximal end of the vitelline or umbilical duct may establish a communication extending between the lower portion of the ileum and the free surface at the umbilicus. In the majority of such cases, however, the diverticulum ends before reaching the umbilicus, being continued to the parietes as an impervious fibrous cord. The production of the various forms of funicular hernia probably follows the abnormal attachments of the vitelline duct, which then, as pointed out by Ahlfeld, induces a continuous drag upon the loops of intestine within the cord, thereby preventing its retirement within the abdominal cavity.

Closely associated with an abnormal position and consequent downward traction of the umbilical cord, clefts of the lower part of the abdominal wall, and even pelvic bones, may occur. Ectopia of the urinary bladder, resulting from the rupture of the allantois, due to overdistention, following the obstructed exit of the accumulated excretions owing to closure of the urachus without the formation of the usually substituted cloacal passages, is connected with these abdominal lesions, the vesical defect being frequently associated with abnormal adhesion of the gut.

The altered relations of the parts involved in these malformations exert widely extended impressions, resulting in secondary anomalies. Among such induced malformations are obstructed fusions of the Müllerian ducts due to the interposition of a gut attached to the bladder or of a distended allantoic stalk, and resulting in double uteri and vaginæ in all grades of separation, from the mere suggestion of division, as expressed by a cleft uterine fundus, to completely isolated tubes extending from the oviducts to the vaginal orifice; cleft pubes, with the attendant faulty development of the external genitalia, also follows the lesions in question. Imperfect union of the parts going to form these organs may produce the various fissures, as epi- or hypo-spadia, divided scrotum, etc., from which arise the conspicuous forms simulating hermaphrodites. Displacements of the abdominal viscera and even abnormal curvature of the vertebral column, which latter may induce modifications in the formation and position of the lower extremities, are, likewise members of the train of misfortunes referable to the clefts of the lower abdominal wall.

Interruptions in the closure of the neural canal along the dorsal line of fusion occur, as already stated, less frequently than along the corresponding ventral line. Two localities—the cervical and lumbar regions—exhibit an inherent weakness in the walls of the neural tube, being the points at which union is last completed and at which, therefore, the tissues are least capable of resisting undue pressure from within; the sharp flexures which occur at these positions of the canal are probably, as pointed out by His, responsible for the tardy closure and accompanying weakness. Corresponding with this predisposition, spinæ bifidæ are more frequently observed in these particular portions of the neural canal than elsewhere, those occupying the lumbar region, moreover, preponderating. Where the protrusion is small in size, the stretched and thinned out integument still suffices to invest the tumor; with the enormous increase in the dimensions of the latter sometimes seen, the skin no longer is capable of covering the protruding tumor, the sac in such cases being composed of the distended membranes of the cord alone.

Concerning the mode of formation of spina bifida opinions vary; the older and widely accepted view regards augmented intra-spinal pressure, referable to primary hydrops, as the active factor, and the ununited arches and protruding sac as results of a process of displacement largely mechanical. Other observers, on the contrary, regard these defects as the expressions of arrested development which owes its origin to deeply seated causes affecting the skeletal axis. The symmetry of the vertebral defects shows that they must originate at an early period of fœtal life when formative processes were active in the differentiation of the primary material. The experimental investigations of Richter,[21] likewise, do not support the view that the spinal dropsy or amniotic pressure is to be regarded as the fundamental cause of spina bifida.

The malformations involving the cephalic expansions of the neural tube are also the subject of divergent opinions. The older view, supported by Dareste, Marchand, Perls, and others, attributes to the amnion, as the result of the pressure and obstruction caused by its abnormal adhesions and constriction, the most important rôle in the arrest of development. Ahlfeld, on the other hand, considers that the primary condition is one of abnormal intracranial pressure which results in the rupture of the very early cerebral vesicles, followed by the absorption and disappearance of the ragged edges of ruptured sac, so that later, when these cases usually first come under observation, the cranial basis lies exposed and the original conditions are masked.

Opposed to these non-mechanical theories as to the mode of these malformations are the views of Ackermann,[22] Quicken,[23] and others, who regard these imperfect cephalic developments rather as the results of defective formative energy and insufficiency of formative material than as secondary defects induced by pressure. In view of the frequent association of these cephalic defects with those of the neural canal, it is highly probable that similar forces are responsible in both localities for the arrested development. As consequences of the imperfectly expanded cranial base, and the not infrequently associated vertebral defects, the proportions of the face and the direction of its axis are materially changed, thereby producing the striking "frog-headed" physiognomy so characteristic of an encephalic monster.

Closely related to these deviations in the cephalic developmental processes stand the variations in the closure of the anterior end of the neural tube which produce the conspicuous series of cyclocephalic monsters, whose brief consideration may here find place. Both the view that cyclocephali result from the fusion of two eyes originally distinct, and that ascribing them to failure of differentiation of the two eyes from a condition of primary unity, have been superseded by the more recent explanation by Dareste,[24] by whom the cyclopian features are regarded as directly dependent upon the primary imperfect development of the anterior cerebral vesicle.

The differentiation of the lateral diverticula, or optic vesicles, which under normal conditions are formed, is but partially accomplished, owing to the imperfect development of the anterior cerebral vesicle in consequence of the premature closure of the neural plates forming this portion of the nervous tube. As a result of this closure, an insufficient involution of ectoderm takes place whereby the amount of material available in the formation of the optic vesicles is greatly reduced. When this closure of the cerebral vesicle occurs very early but a single me-

dium optic vesicle is formed, resulting in the production of the characteristic feature of these monsters. In cases where the closure takes place later, affording greater opportunity for advanced development, two imperfectly differentiated optic vesicles are present, from which two eyeballs, more or less closely approximated, arise, the degrees of proximity and fusion depending upon the completeness of the differentiation of the optic vesicles as separate sacs. The cause of the primary arrest of development affecting the anterior cerebral vesicle, Dareste is disposed to attribute to anomalous growth of the amnion, in consequence of which the expansion of the brain vesicle is unable to proceed to the usual extent.

As secondary defects, dependent upon the abnormally situated central optic vesicle and the faulty development of the anterior cerebral sac, deviations and displacements of the naso-frontal process take place with corresponding conspicuous changes in the face. The absence of the central process allows the approximation of the superior maxillary divisions of the first visceral arch, by whose fusion the oval opening assumes a characteristic triangular form. Immediately above the mouth the closely approximated, or single, visual organs take up their position, the displaced naso-frontal process lying higher and often resulting in the development of the characteristic proboscis.

The anomalies owing their production to the abnormal persistence of canals whose function ceases before or at the time of birth are usually inconspicuous, but, at the same time, may induce conditions incompatible with post-fœtal life. The peculiarities of the fœtal circulation are not infrequently retained as a patulous foramen ovale or pervious ductus arteriosus. Variations in the plan of suppression among the aortic arches of embryonic life give rise to the conspicuous anomalies of the great vessels near the heart; not only are transposed aortæ, double aortæ, and deviations in the origin of the subclavian and carotid arteries to be referred to deviations from the usual fate of the embryonic aortic bows, but, likewise, the transposition of the associated viscera. Instances of the retention of the embryonic arrangement of the venous system are also occasionally seen, as in many anomalies of the great veins near the heart. The presence of Meckel's diverticula, and, in extreme cases, the formation of an artificial anus, find their explanation in the persistence of the lumen of the vitelline duct. Likewise, the retention of the allantoic stalk in a pervious condition, instead of the usual transformation into the fibrous urachus, may establish an unnatural exit for the contents of the urinary bladder; such conditions are usually induced by obstruction, during fœtal life, of the more usual channels. Partial retention of the lumen of the allantoic stalk may result in the formation of cysts. Imperfect obliteration of the thyro-glossal duct may contribute to the production of cervical fistulæ.

III. *Malformations produced by fission, either partial or complete*—

a. Of the primary embryonal cell-mass;

b. Of the partially differentiated individual organs.

The malformations comprising the third group—those derived by fission—include the most conspicuous results of developmental deviation, forming a series beginning with the limited fission implicating a single digit, and ending with the extreme division presented by those double monsters in which union is alone maintained by the limited isthmus of attachment, as between the sternum, pelvis, or head.

The production of double monsters has long been a subject of diligent study and ingenious speculation, and even at present it constitutes a biological problem regarding many details of which there is still much difference of opinion.

The once generally accepted and brilliantly supported theory, that double monsters result from the fusion of two separate and independent embryos, may be regarded as now entirely obsolete, modern embryologists agreeing, at least so far, that multiple monsters arise from a single ovum.

Regarding the further question, however, as to whether these monsters originate by the union of two originally distinct embryonic areas upon a single ovum, or whether they result by the cleavage of a single blastoderm, opinions still fail to accord. The former supposition recognizes primitive duality, followed by fusion, the latter primitive unity undergoing subsequent fission.

In addition to the older authorities upholding the fusion theory, B. Schultze, Panum, and especially Dareste, have given this view their support, while Rauber, Gerlach, and others accept it with more or less important modifications. Dareste, while accepting the doctrine of primitive duality, insists that union can only take place in the very earliest stages, and then only as the expression of a special inherent predisposition.

The supporters of the fission theory number many of the most distinguished older investigators, and probably the majority of the embryologists of to-day. The fission theory, as presented by Ahlfeld, one of its most ardent advocates, suffices for the explanation of all forms of double monsters. The primitive undifferentiated embryonic cell-mass may undergo cleavage, in the direction of the future embryonic axis, in varying degrees. When the division is complete, the two resulting halves lie at first parallel, and are capable, under favorable conditions, of developing into homologous twins; when incomplete, the divided parts may subsequently separate, while the attached portions constitute the common bond of union, either anterior, posterior, or middle, as illustrated in the accompanying drawings (Figs. 386 to 389) of actual double monsters of different types of fission observed in the development of avian ova. By the variations in the intensity of these forces all degrees of deflection, from a position of almost parallelism to one of extreme divergence, as head to head, is possible. Ahlfeld regards the fission theory as sufficient for the explanation of all forms of double monsters, and does not admit the necessity of seeking aid from other theories.

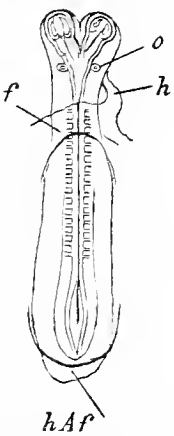

Fig. 386.—Chick Embryo of about Forty Hours, showing limited anterior cleavage. (Dareste.) *rAf*, *hAf*, cephalic and caudal folds of amnion; *h*, heart; *o*, primary otic vesicles.

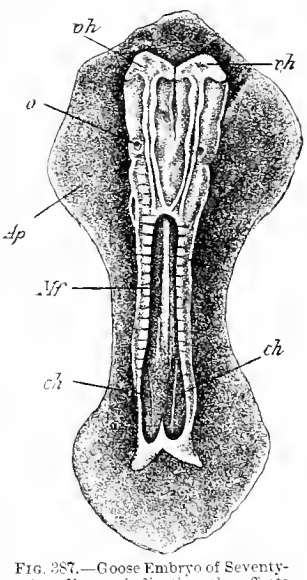

Fig. 387.—Goose Embryo of Seventy-two Hours, indicating the effects of coincident anterior and posterior cleavage; the two resulting divisions are connected by the isthmus of undivided tissue. (Reichert.) *Ap*, area pellucida; *vh*, anterior brain vesicles; *o*, primary otic vesicles; *Mf*, medullary folds; *ch*, chordæ of the divided parts.

Gerlach[25] regards the production of double monsters as far more variable, and opposes the passive cleavage ascribed to the embryonic cell-mass by Ahlfeld, attributing, on the contrary, to the embryonic trace an active participation in the division, the controlling predisposition to which must reside within the cells even before differentiation. This "bifurcation" Gerlach considers especially active in producing anterior or cephalic duplications; the corresponding posterior or caudal cleavage is referred by this author to the partial union or "copulation" of separate but converging traces proceeding from the posterior margin of the germinal

area. Debierre [26] and Klaussner [27] also hold the fission theory as inadequate to account for all forms of double monsters; the former concludes that both fission and fusion may take part, while Klaussner declares that the genesis of such monsters depends upon primary plurality of the embryonic area, and upon fission with post-generation.

The inadequate observations on early mammalian double monsters, together with the fact that the youngest human double monster was already four weeks old (Ahlfeld), still farther adds to the uncertainty of conclusions regarding man and the higher types. Notwithstanding the incompleteness of our knowledge in many points concerning these interesting questions, it must be admitted, we believe, that to fission of the primary embryonic trace must be referred the origin of the great majority of the double monsters encountered, and that, in the present state of our knowledge, we are warranted in

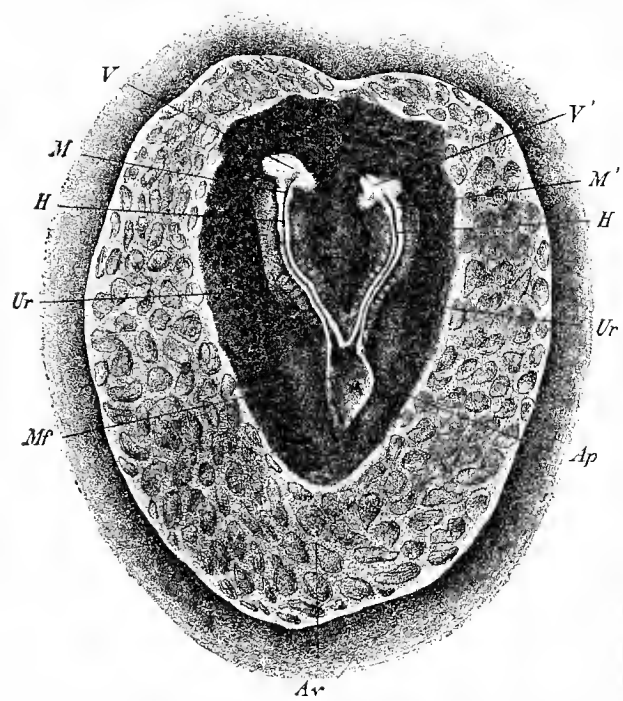

FIG. 388.—Double Chick Monster of Forty-eight Hours. Marked anterior cleavage has taken place, with subsequent divergence. (Gerlach.) *Ap*, area pellucida; *Av*, area vasculosa; *V*, *V'*, *M*, *M'*, *H*, *H'*, respectively the anterior, middle, and posterior primary brain-vesicles; *Mf*, the still widely open medullary folds; *Ur*, the somites or primary segments.

accepting, provisionally at least, the explanations offered by this theory.

The most pronounced effect of the cleavage forces results in the complete division of the cell-mass into two separated portions. Each of these may undergo independent development, the two, under favorable conditions, developing into *homologous twins*, characterized by remarkable physical similarity and the same sex.

In those cases, however, where the cleavage forces effect but partial division of the original embryonic mass, the production of the conspicuous double monsters takes place. The degree of the duplication varies from the slight splitting of the cephalic end of the notochord, the resulting condition presenting no external evidences of its existence and being only accidentally discoverable, to the almost unrestricted separation resulting from the coincident anterior and posterior cleavage where, as in xiphopagus, a narrow bridge of remaining tissue alone establishes continuity.

As an extremely rare occurrence, a repetition of the cleavage may take place in one of the separated embryonic segments, thereby producing a third, which, in the case of complete fission, would form one of the group of homologous triplets; partial cleavage of one of the segments would produce a composite monster of the triple type. Such cases must, obviously, belong to the rarest of anomalies, and when occurring would be prone to unequal development with the suppression of the weaker embryos. Multiple human monsters in excess of triplets have never been observed. When the almost entirely separated embryonic segments undergo equal development and growth, the resulting individuals may be capable of maintaining an almost independent existence, as in the case of the celebrated Siamese twins; not infrequently, however, the segments are affected by unequal development and growth, the disparity becoming more marked with time. From a condition of equality, the weaker embryo becomes more and more dependent upon its stronger mate, until the relations become pronounced as some form of parasitic monster. In the observation of the later stages of growth, when the condition of inequality is already well emphasized, sight must not be lost of the fact that at an earlier period both embryos were of equal dignity, although the possible presence of a shapeless acardiacus attached to a moderately well-developed fœtus at first glance seems little in accord with such condition.

The explanation of the series of obscure parasitic monsters, represented by the different "inclusions," is found in the assumption of duplications, either posterior or anterior, where, as pointed out by Cleland, the two segments are primarily united at a point variably distant from the upper end of the vertebral column. With the subsequent unequal growth of the two embryos, the less developed finally comes to lie within the body of the stronger to an extent dependent upon the position of the primary union, and upon the stage of development and growth to which the weaker part attains. Where the "parasite" remains relatively free and well nourished, the relations between the two may approach those presented by the classic example of the Genoese Colloredo, and by the young Hindoo, Laloo, now living and about twenty years of age. These "inclusions" present their extreme in the obscure tumors attached to some part of the head, as the hard palate (epignathus), lower jaw (polygnathus), orbit, and other parts of the cranium, in which cases the union of the two embryonic segments is situated at the anterior extremity of the vertebral axis, and the weaker segment has, either from the first undergone but slight development, or, as advocated by Cleland, suffered a separation. The part remaining attached to the main stem becomes enveloped within the tissues of the stronger embryo to constitute the contents of the tumor, the position of whose external attachments determines the designation which it receives. In the case of the "congenital sacral" tumors a somewhat modified process must be recognized, since, as held by Cleland, the bony parts within these tumors are the remains of the fused adjoining lower limbs of, at one stage, double sets of extremities, resulting from fission involving the embryo as far as the sacrum. The adjacent left and right limbs of the duplications remain undifferentiated and fused, and, undergoing subsequent atrophy, remain as the contents of the sacral tumor; it follows, therefore, that the limbs which develop really represent the right and

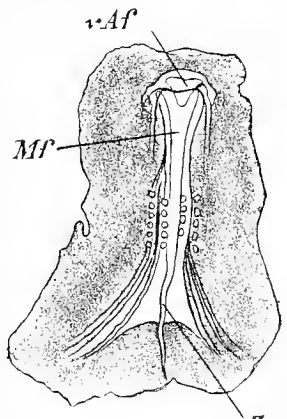

FIG. 389. — Chick Embryo of Thirty-six Hours, showing posterior or caudal cleavage. (Ahlfeld.) *Mf*, medullary furrow divided toward its caudal extremity into the diverging grooves, separated by the median fold (amniotic (?)); *Zw*; *v.Af*, anterior or head fold of amnion.

left members, not of the same, but of two pairs of extremities.

The included fœtus ordinarily lies enclosed within a sac closely united with the surrounding organs; from these latter blood-vessels form communications which supply the nutrition requisite for the existence of the parasite. Should the remaining parts of the included embryo come to rest upon the actively growing tissues destined to form the sexual glands, these parasitic structures become surrounded by the tissues of the future testicle or ovary, and later give rise to inclusions within these organs. These rare conditions must be clearly distinguished from the relatively frequent dermoid cysts occurring within the testicle and ovary: while in the former cases the remains are parts of the atrophic supernumerary embryonic segments, arranged with, at least, a suggestion of order, the contents of the dermoid cysts represent heterogeneous, isolated, and usually ectodermic, tissues of limited variety.

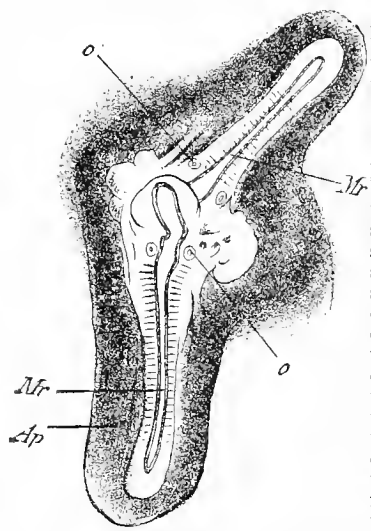

FIG. 390.—Double Chick Monster Resulting from Posterior Cleavage and Subsequent Great Deflection of the Separated Segments. (Rauber.) Such monsters suggest to some authorities the assumption of the possible occurrence of the fusion of at first isolated embryos. *Mr*, medullary furrows; *o*, primary otic vesicles; *Ap*, area pellucida.

Contrasted with the foregoing results of complete or partial dichotomy involving the entire embryonic cell-mass stand the limited duplications arising from the fission of the cell-areas forming the individual organs. Such duplications affect almost every important viscus in the body.

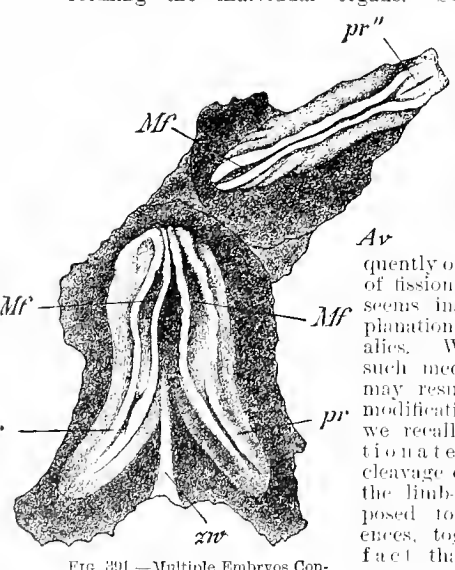

FIG. 391.—Multiple Embryos Contained within two Closely Approximated Area Pellucidæ Occurring in Chicken's Ovum, after sixty Hours' Incubation. The smaller area contains a single embryo, the larger an embryo which has undergone complete posterior cleavage. (Rauber.) *Mf*, medullary furrows; *pr*, *pr'*, *pr''*, primitive streaks; *zw*, median ridge; *Av*, area vasculosa.

The assumption that the obstruction caused by the folds of an abnormally adherent amnion is chiefly responsible for the frequently observed examples of fission in polydactylism seems insufficient in explanation of these anomalies. While, no doubt, such mechanical forces may result in important modifications, yet when we recall the disproportionate infrequency of cleavage of those paris of the limb-buds most exposed to external influences, together with the fact that numerous instances of polydactylism occur among the anamniota, as the amphibians, and the conspicuous transmission of such anomalies by heredity, through several generations, it is evident that the production of these anomalies lies in a much more deeply seated and less local cause. As observed by Pott,[29] the conditions producing polydactylism, adactylism and syndactylism are closely related, being the variously modified expressions of the same inherent differential forces that, under usual conditions, result in the separation of the common cell-area into the normal number of well-defined digits. Where these forces of differentiation and separation, which seem to be possessed by all parts of the embryo during some stage of embryonic life, are stimulated as by excessive presence of formative materials, their action may be exerted far beyond the usual limits, resulting in repeated and extensive more or less perfect cleavage. These divisions commonly are limited to the distal segment of the embryonic limb, producing the frequently encountered supernumerary digits, fingers or toes; much less frequent are divisions implicating the remaining segments, duplications of the entire arms and legs being extremely rare. A remarkable example of cleavage of the upper extremity is recorded by Burnett,[28] where the entire arm has suffered repeated partial division.

Excessive activity of the differentiating forces results in the cleavage of the cell-areas destined to become various parts of the body; examples of such excessive action are particularly noticeable in the formation of such series as the ribs and vertebræ, as well as the muscles, vessels, and nerves, their production supplying the "variations" of the anatomical text-books. Many organs occasionally present more or less complete duplications, either as the result of early fission of the primary cell-mass, or of secondary division induced by encroachments of neighboring tissues. Among the organs occasionally undergoing such cleavage are the tongue, uvula, epiglottis, bronchiæ, pulmonary lobes, stomach, intestines, liver, gall-sac, pancreas, spleen, kidney, ureter, urinary bladder, sexual glands, and mammæ. In connection with the production of supernumerary mammary glands, the recent investigations of O. Schultze[30] are very suggestive, since it is shown that special embryonic areas, or "milk-lines," extend on either side as far as the groin, the permanent glands resulting as the development of certain limited areas along these tracts. While the occurrence of mammary glands on the anterior surface of the body thus finds suggestive embryonal conditions, the instances of mammæ situated on the thigh being also readily regarded as extensions of the primary milk-lines, the occurrence of supernumerary glands on the back, as sometimes observed, seems to call for further explanation. The assumed transplantation of the divided original gland-area seems less plausible than to regard the appearance of these glands in such unusual positions as the expression of perverted differentiation of widely distributed epidermal structures, the mamma arising as but the higher specialization of the ectodermal tissue producing sebaceous glands. Supernumerary mammary glands occur in men with far greater frequency than is usually supposed, as shown by the examinations by Bardeleben[31]; the apparently greater frequency in women arises from the fact that the secretion of milk within these structures, after childbirth, calls attention to the existence of anomalies never before suspected.

The Artificial Production of Malformations. — The origin of double and other monsters has always presented so much of interest, but at the same time of uncertainty, that the hope of adding to our understanding of the methods and conditions of their production long ago induced observers to undertake the artificial production of such malformations. For evident reasons, these attempts at experimental investigations have been limited to the lower forms. While the results of such investigations cannot be directly applied to man, yet they are of value in pointing out facts which possess a probable bearing upon similar processes taking place in the higher mammalian types. In applying the deductions derived from experiments with the lower classes of vertebrates, the inherent differences in the processes as affecting the totally segmenting alecithal mammalian ovum and the partially segmenting telolecithal eggs of the fishes and birds, must not be forgotten.

The possible causes influencing the production of malformations may be arranged in three groups:

I. Anomalous conditions of the sexual elements:

a, Of the female element—the ovum; *b*, of the male element—the spermatozoön; *c*, of the union of sexual elements, resulting in abnormal fecundation and segmentation.

II. Direct mechanical impressions.

III. Anomalous conditions of environment of the embryo, including thermic and respiratory changes.

It is evident that the experimenter has little control over the modifying conditions embraced in the first group, and that these, for the purposes of his attempts at artificially inducing the production of malformations, must be largely ignored. Of interest are the observations of Born [32] on fish eggs, since the fact seems established that the ova of certain females showed especial tendency to yield double monsters, the predisposition remaining practically constant and unchanged notwithstanding variations in the source of the fertilizing male elements. The segmentation of these ova appeared to be normal.

So far, there is no reliable evidence pointing to anomalous conditions of the male sexual elements as being responsible for abnormal development. The double-headed spermatic filaments not infrequently seen, and to which the production of double monsters has sometimes been attributed, are to be regarded as variations in the development of the spermatic elements themselves, rather than as cells endowed with unusual powers of fertilization.

The connection between the entrance of more than a single spermatozoön into the ovum at the time of fertilization, and the induction of abnormal segmentation and subsequent maldevelopment, has been maintained by Fol,[33] and formerly also by O. Hertwig; the more recent investigations of the Hertwig Brothers,[34] however, do not support the supposition that polyspermia produces double monsters. The relation between double spermatozoa and the imperfect expulsion of the second polar body as anticipating the formation of double monsters, as suggested by Windle,[35] lacks further confirmation; and so does, likewise, the hypothesis advanced by Dareste,[36] that multiple pronuclei follow the penetration of more than one spermatic element.

The possibility of influencing development by the application of mechanical impressions early invited the consideration of experimenters. These mechanical influences, brought to bear upon the ovum with a view of modifying development, have been:

a, Abnormal position; *b*, disturbed equilibrium; *c*, direct mechanical injury.

The elder Geoffroy Saint-Hilaire, by his success in producing malformations by incubating eggs placed in abnormal positions, has merited the distinction of being regarded as the founder of experimental teratology.

Thirty years later, Liharzik [37] succeeded in distinctly modifying chick embryos by change of position during the latter half of incubation, when the chick normally lies with its axis corresponding with the longer diameter of the egg, the head usually occupying the broader end of the egg. Recognizing this normal relation, Liharzik placed the eggs vertically, in some cases with the larger end uppermost, in others with this extremity down. The increased nutrition affecting those parts, whether head or tail, which were dependent and, therefore, aided by gravity, was manifested by the distinctly recognizable increase in size of those portions which had occupied the lower end of the egg. Dareste [38] also obtained positive evidence of influenced development by adopting the vertical position, while, more recently, Strahl and Gasser [39] fixed the yolk so that development proceeded while the germinal area lay beneath, and thereby produced a partial inversion of the viscera which, apparently, depended upon the abnormal position for its cause.

The disturbing influences of violent agitation have long been known and successfully applied to the production of malformations by Valentin, Knoch, both the elder and younger Geoffroy Saint-Hilaire, Lombardini, and Dareste. The latter experimenter observed that when eggs are incubated immediately after violent agitation, as after railroad transport, they usually soon die, while, on the contrary, if a period of rest intervene before incubation development proceeds normally. Eggs violently shaken by a machine for some twenty minutes before incubation gave rise to many malformations, including exencephalus, cyclocephalus, spina bifida, etc. Some eggs, however, notwithstanding their maltreatment, passed through the cycle of normal growth.

Attempts at still more profoundly influencing the course of development have been made by the direct injury or mutilation of the early embryonic cell-mass. Schrohe [40] incised and punctured the germinal area with the hope of producing double monsters, but with the results of inducing but single deformities. Rauber's attempts at causing the formation of double monsters by division were also negative; his conclusions, that it is not possible to produce such malformations by mechanical injuries, are endorsed by Panum and Dareste. In this connection the quite recent experimental investigations of Driesch [41] on the segmentating ova of echinus, and, still later, of Wilson [42] on the earliest stages of amphioxus, are extremely suggestive. In these experiments, by the separation of the blastomeres of the earliest stages of segmentation, it was possible to obtain multiple embryos, either as isolated individuals, or, as often happened in the experiments on amphioxus, as double monsters in various stages of separation. These investigations are important as emphasizing the primary differential equality of the early blastomeres, a single segmental element, in some cases observed by Driesch, sufficing to produce a perfect individual of diminished size.

Further attempts to produce anomalous embryos have been carried out by Warynski and Fol, who applied the thermo-cautery to embryos, and concluded that cœlosomia and symelia are the only malformations directly referable to the amnion; Gerlach [43] also cauterized the anterior end of embryos with the view of producing exencephalus, but with only partially satisfactory results. Electricity in various forms has been employed by Lombardini, Maggiovani, Windle, and others, but this agent seems capricious and uncertain in its results.

The experiments whereby the supply of heat and oxygen has been affected have yielded the most important results. As long ago established by Réaumur, the most favorable temperature for incubation is about 40° C. By keeping eggs at a temperature of 41° to 42° C., Dareste was able to obtain in twenty-four to thirty hours, embryos which had attained a development corresponding to that usually reached only at the third day; on the other hand, a reduction to 30° C. retarded development fully one-half. Variations in the form and development of the germinal, and especially the vascular, area seem frequent accompaniments to these thermal changes. A continuous slight elevation above the normal temperature hastens development but retards growth, and often results in the production of dwarfs. Out of seventy-eight eggs incubated at a reduced temperature, Richter [44] obtained five malformations, three spinæ bifidæ with exencephalus, and two exencephali alone.

Modifications in the amount of oxygen having access to the egg have been carefully studied by a number of experimenters. While the effect of an abnormally abundant supply of oxygen must be regarded as still undetermined, the deleterious influences of a diminished supply are conclusively established. In the experiments affecting the respiratory interchange of gases, advantage has usually been taken of the fact that through the porous egg-shell the air gains access to the ovum. Various devices for rendering the shell more or less impervious to gases have been employed, the favorite method being the application of varnish. Dareste has called attention to the precaution of coating freshly-laid eggs, since after the formation of the air-space the contained oxygen suffices for development for a certain length of time. The elaborate experiments of this author confirmed the investigations of the earlier observers as to the efficiency of these methods of influencing development, especially the

development of the vascular area and the blood-corpuscles, thereby establishing an anæmic condition. Dareste concluded, moreover, that the restricted supply of air bore no direct relation to the malformations.

The methods adopted by Gerlach in his experimental investigations are of especial interest from the fact that the results are more nearly positive than those of any former experimenter. Recognizing that the growth and proliferation of cells are always influenced by the supply of oxygen, Gerlach assumed that by restricting the interchange of gases to a **V**- or **Y**-shaped area, so placed that it would correspond to the anterior part of the germinal area, it might be possible to alter the arrangement of the cells, by compelling a new disposition in their search after oxygen, to the extent of producing an anterior bifurcation. Of sixty eggs so treated, nineteen exhibited variations which Gerlach attributed directly to the modified conditions of respiration. Of these deviations, two were unmistakable anterior duplications. It is to be remembered, however, that such malformations probably occur, under ordinary conditions, more frequently than supposed, and the direct causal relation between the two fissions and the especial treatment of the eggs is by no means beyond question.

Gerlach and Koch,[45] and later Koch,[46] studied the connection between restriction of air and the production of dwarfs, but they conclude that the retarded growth consequent upon such conditions results not in true dwarfs, but only in poorly developed embryos.

Review of the foregoing experiments in the artificial production of malformations emphasizes the fact that certain disturbing influences, as violent agitation, marked thermic variations, and restricted supply of oxygen, are all forces capable of profoundly impressing the early embryonic cell-mass, and of secondarily inducing more or less conspicuous malformations. And further, as pointed out by Dareste, and more recently emphasized by Windle,[47] that there is no definite relation between the nature of the disturbing influence and the character of the resulting malformation, the same anomalies being produced by various methods. On the other hand, notwithstanding a wide variation in the nature of the disturbing agents, the deviations of development are largely those referable to impaired nutrition, as expressed by the defective development of the vascular system.

Whatever may be the success of future investigators in producing at will certain types of malformations, it must be admitted that at present, at least, experimental teratology is capable of yielding results which are suggestive rather than definite. *George A. Piersol.*

MALT (*Maltum*, U. S. Ph., 1880). The official directions given in the United States Pharmacopœia for the preparation of this product are as follows :

"Malt, in coarse powder, not finer than No. 12, one hundred (100)parts ; water, a sufficient quantity. Upon the powder, contained in a suitable vessel, pour one hundred (100) parts of water and macerate for six hours. Then add four hundred (400) parts of water, heated to about 30° C. (86° F.), and digest for an hour at a temperature not exceeding 55° C. (131° F.). Strain the mixture with strong expression. Finally, by means of a water-bath, or vacuum-apparatus, at a temperature not exceeding 55° C. (131° F.), evaporate the strained liquid rapidly to the consistence of thick honey. Keep the product in well-corked vessels in a cool place."

The historical references, detailed description of the processes of manufacture and peculiarities of the finished product, as given by Professor Bolles (REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, Vol. IV., 1887, p. 637), are sufficiently full for our present purpose, and need not therefore be touched upon. The almost universal employment of malt preparations, especially liquid malt-extracts, by physicians and by the laity, however, seems to warrant a critical study of their value from a therapeutic standpoint. This naturally implies an investigation of the composition of malt, its properties as a food-substance from a physiological point of view, and finally, an estimate of its virtues alone, or combined with other medicaments, in the treatment of disease. And, inasmuch as there is a popular demand for these products, some reference should also be made to adulteration, and the addition of foreign substances—principally antiseptics, to prevent fermentation.

COMPOSITION.—The manufacture of malt consists essentially of four different processes, viz. : *Steeping*, *couching*, *flooring*, and *kiln-drying*, which result in decreasing the weight of the grain (about 20 per cent.), but are attended with an increase in bulk (3 to 8 per cent.). The entire manipulation should be considered as succes-

sive steps of the same operation, since the malt contains, in somewhat altered arrangement, the substances found in the grain; malting merely effects the transformation of these substances, through the influence of heat, moisture and the amylolytic action of *diastase*, an unformed ferment (*enzyme*) which is a constituent of malt to the extent of from one to two per cent. (Hagar). Through the action of diastase—manifested within an hour after grain is put to steep—whose properties are similar to that of *ptyalin* from the saliva and *amylopsin* from the pancreas, the insoluble starch of barley is converted into dextrin and glucose — sometimes called grape-sugar. Thus, the outline of Proust (*loc. cit.*) shows that malt contains nineteen per cent. less starch and cellulose than barley, ten per cent. more sugar, eleven per cent. more dextrin, while the amount of gluten is lessened by two per cent. It should be stated in this connection that, while the object of "malting" is to produce the maximum of sugar by the action of diastase, it is not desirable that this action should be entirely exhausted, and therefore, at a certain stage of the operation, this process is arrested by kiln-drying; under favorable circumstances —heat and moisture—this fermentation is re-kindled.

Qualitative tests for *diastatic activity* are extremely simple. A quantity of malt is added to hot water and dissolved by constant stirring; then a small portion of starch is added in like manner, and in the course of a few minutes the iodine test is applied.

The *soluble extract* in a good malt suitable for brewers' use, is, according to Ure, 66.8 per cent.; it contains in addition, insoluble matter, 26.7, and moisture, 6.5 per cent. To determine the proportion of *insoluble matter*, a definite quantity is measured by weight and dried by heat from boiling water; the remaining powder is then put in cold water and heated. The soluble extract is then decanted off and the residue dried and weighed and the percentage calculated.

The process of diastatic fermentation is by hydration (Hoppe-Seyler), as will appear later on. The amylolytic power of diastase is about the same as the proteolytic power of a good pepsin; that is, diastase will convert starch into glucose in the proportion of 1 to 2,000, while pepsin converts albumin into peptone in the same proportion, although recent improvements in the manufacture of pepsin enable manufacturers to produce a much more concentrated article (1 to 6,000).

Liquid malt-extracts are simply weak solutions of ordinary malt, very much like beer, and usually contain a variable proportion of alcohol, a small percentage of carbonic acid, with more or less solid extract, but for none of them can be claimed any distinct diastatic property. These preparations hold in solution the products of diastatic activity, dextrin and sugar, which renders them "sweet" and palatable, while the alcohol is not in sufficient amount to interfere materially with the proper performance of the digestive functions; indeed, in the case of elderly persons, it may prove a decided benefit. Carbonic acid is also acceptable to the stomach; but the percentage of "*solid extracts*" in these products furnishes no criterion as to their intrinsic value, as will be shown presently.

From an examination and analysis of thirteen different samples of liquid malt-extracts, Leffmann (*Medical News*, January 28, 1893) found that all save one contained alcohol in small proportion—none as high as eight per cent., and that the solid extract ranged from 5.1 grammes to 16.06 grammes for each 100 c.c. Moreover, three of the samples contained appreciable amounts of salicylic acid.

Adulteration.—The temptation to sophisticate malt arises from the great care required in the process of malting; if the diastatic power be destroyed by excessive heat, the malt possesses no nutritive or digestive value. Again, in sections of the country where malting is extensively carried on, manufacturers may employ "ungerminated" grain, *i. e.*, grain that has been subjected to "heating," and has thus lost its vitality. As a result of wet seasons, therefore, malt may be of a very inferior quality — possessing but slight diastatic power, yet showing a large percentage of insoluble matter.

Most serious objections are urged against the employment of salicylic acid as an antiseptic, since it is harmful if taken in too large quantities or too long continued, and besides, like all other antiseptics, it arrests or suspends diastatic activity. Now, while this is true in general, it may not apply uniformly to malt-takers and beer-drinkers, because we know that even in the absence of diastatic power this class generally present a rotund, florid, sometimes a bloated appearance—due to the deposit of fat from the absorption of sugar—and frequently suffer from rheumatic affections; hence the introduction of salicylic acid free from impurities may possess negative value, (1) by enacting the rôle of an antiseptic in the alimentary canal, (2) by lessening the diastatic activity, thereby preventing the rapid conversion of starch, and (3) by its influence upon the rheumatic diathesis. This leaves, then, for the liquid malt-extracts containing salicylic acid, nothing of special value except the converted sugar and a small proportion of alcohol.

Incompatibles.—The following table (after Hermann Meyer and Brunton) is introduced to show the strength in watery solution of the different drugs which arrest the action of diastase, from which it will be observed that, while chloroform and creasote, even in saturated solution, have very little or no deleterious effect, corrosive sublimate in a solution so weak as 1 to 50,000 destroys the ferment. Thus salicylic acid in the proportion of one grain to ten ounces (approximately) is sufficient to arrest the action of diastase:

Alcohol, 1 to 3.	Corrosive sublimate, 1 to 50,000.
Benzoate of soda, 1 to 100.	Creasote, no action in sat. sol.
Benzoic acid, 1 to 1,025.	Eucalyptus oil, acted only in excess.
Borax, 1 to 100.	Glycerine, 1 to 2.
Bromine, 1 to 5,070.	Iodine, 1 to 4,125.
Carbolic acid, 1 to 30.	Mustard oil, only lessens action in sat. sol.
Chloride of lime, 1 to 6,613.	Salicylic acid, 1 to 5,100.
Chlorine, 1 to 7,411.	Sulphurous acid, 1 to 8,600.
Chloroform, slight action in sat. sol.	Thymol, slight action in sat. sol.
Copper sulphate, 1 to 6,500.	

Physiological Action.—From the preceding remarks it will be apparent that there is comparatively little to add in regard to the physiological action of malt, either from the standpoint of the clinician or from that of the physiologist; and yet that little is of paramount importance. Malt performs a twofold action in that it is a digestive and nutrient, its virtues being augmented by hydration. Digestibility is the prime element in all food-stuffs, but concentration may seriously interfere with absorption; hence the importance of dilution by water, which is the most efficient medium for the transmission of pabulum through the secreting structures of the alimentary tract (endosmosis). Thus, while concentration is an important factor entering into questions relating to the manufacture and transportation of food products, the very opposite is essential to insure rapid absorption and easy assimilation. But the increased consumption of carbohydrates, while it increases the amount of fat, is at the expense of muscular structures which require nitrogenous material for the maintenance of their integrity, and therefore, too much dependence must not be placed upon the apparent gain secured by the administration of malt and predigested foods of this character. Indications of their unfavorable effects will be manifested by acidity, hepatic and cardiac derangements, and constipation, along with mental hebetude and other evidences of imperfect metabolism.

Contra-indications to the employment of malt preparations in the treatment of children's diseases, more especially those peculiar to summer and autumn, should be noticed, viz.: evidences of fermentation in the stools. When this condition is present, carbohydrates must be omitted and nitrogenous food substituted.

The dangers arising from the small percentage of *alcohol* in the liquid malt-extracts have been unduly magnified, as we have ample evidence of its value as a reconstructive. In suitable amounts—*with meals*—alcohol improves the

appetite, favors digestion, lessens the elimination of phosphorus and promotes the excretion of urea, thus enhancing muscular capacity; but we must bear in mind, also, that alcohol *lessens oxidation*—a conservative process in certain wasting diseases—although an effect to be avoided in health. Its obtunding influence upon the nervous system is likewise of medicinal importance, and in the administration of malt preparations we should never lose sight of the physiological functions of the organism, our sole object being to restore and maintain its integrity by the exhibition of remedies adapted to its wants.

There is still another important factor to be considered in connection with the physiological functions of malt. For example, a considerable percentage of cod-liver oil can be incorporated with it in such a manner that the compound is tolerably stable while freely miscible with water, and, therefore, readily assimilable by the digestive apparatus. Now, bearing in mind that malt contains more or less gluten, perhaps a little dextrin, together with some unconverted starch and *insoluble extract*, it is not unreasonable to believe that under normal conditions the contents of the intestine may approach the type of a mucilaginous substance, possessing cohesive properties, and whose viscosity will prove of value in preventing the absorption of poisonous products from the alimentary tract. Physicians readily appreciate the value of starch enemata in irritable conditions of the lower bowel, although but few understand the *modus operandi* by which these benefits are secured. Starch enemata are of service, not merely because they have a quieting effect upon the terminal filaments of sensory nerves in the mucous structures, but rather on account of their adhesive qualities, which enable them to lay hold of poisonous substances in the course of elimination, thus preventing them from coming into contact with the delicate and inflamed tissues. While the old idea has long been accepted as a clinical fact, it was nothing more than a temporary hypothesis or make-shift, and is promptly set aside to make room for the scientific fact upon which it depends.

And just here should be pointed out the marked similarity or analogy between the conditions which obtain in the small intestine when malt is administered and that of the lower bowel when a starch enema is introduced. This explanation not only sheds new light upon the incidental physiological action of malt, but it puts the entire theory of the therapeutic action of emulsions upon a scientific basis, in keeping with the results of clinical observation. Heretofore the causes which were actually responsible for the wonderful improvement following the exhibition of comparatively small quantities of malt, cod-liver and petroleum oils, as well as other remedies in the form of emulsion, have been scarcely realized, because the physiological functions of the emulsionizing agents were overlooked, or but imperfectly understood. Notwithstanding the fact of its being a negative virtue, it is, nevertheless, a factor of material significance.

THERAPY.—The most important therapeutic application of malt consists in its employment for the relief of *intestinal affections* dependent upon imperfect intestinal digestion of starchy foods and subsequent fermentation. In this class of cases the carbohydrates should be restricted, bread only being allowed, and the patient instructed to masticate it thoroughly in order to incorporate with it the *ptyalin* of the saliva, which serves to break up the starch granules before entering the stomach. Occasionally *amylopsin* may be added with benefit. This method of treatment will be found available in a very large number of cases of intestinal indigestion associated with *chronic disease*, especially *pulmonary affections*, because, as has already been shown, carbohydrates are fat-producers. They do not, however, increase the capacity of the muscular system, and may, therefore, do harm by lessening oxidation and obstructing elimination. Shortness of breath, cardiac weakness, or hepatic insufficiency with acidity of the stomach and diminished urinary excretion demand their prompt discontinuance and a complete re-arrangement of the dietary.

Malt enjoys deserved popularity as an adjuvant in *convalescence* from protracted illness, as an auxiliary and digestive in the case of *nursing women*, and to a limited extent in the treatment of all *debilitated conditions* of the system, but its continuous or indiscriminate use will eventually result disastrously. Like all other remedial agents, its medicinal employment requires the discriminating judgment of the conscientious and intelligent physician.

In the treatment of *summer diseases*, in both adults and children, malt possesses a high degree of utility, but it is only adapted to the cases in which the stools are putrid and foul-smelling. Where the stools are sour-smelling, due to starchy fermentation, malt and malted products are of secondary importance, as they have no influence upon the micro-organisms or other poisons associated with the intestinal disorder. Indeed, there is good reason to believe that the popular method of treating this class of affections by the exhibition of "*barley-water*" has been productive of greater mortality rates than would have occurred had all treatment been abandoned. Science absolutely condemns the practice, and clinical observation emphatically indorses her teachings. The personal experience of Dr. Benjamin Ward Richardson, published in the *Æsclepiad* about a year ago, covering the untoward effects of oatmeal and barley-water, should be critically studied by every general practitioner.

ADMINISTRATION.—Malt (U. S. Ph.) may be given in doses of *one or two drachms*, either with meals or two hours later. Liquid malt-extract should be given *with meals*—one or two wineglassfuls.

To meet special demands in the case of malnutrition, malt may be combined with a number of reconstructive medicaments, as follows: Malt with quinine, iron, and strychnine; malt with hypophosphites; malt with peptone; malt with cod-liver oil—but not to exceed the proportion of *ten per cent.* *John Aulde.*

MALVERN. A spa of ancient repute in Worcestershire, England.

LOCATION.—Malvern is prettily situated in a beautiful part of Worcestershire, at an elevation of five hundred and twenty feet above the sea. Bradshaw says that the town of Malvern is beautifully situated on the slopes of the Malvern Hills, which rise to the height of fifteen hundred feet above the sea-level. These hills are traversed by roads and paths easy of ascent. From their summit a succession of the grandest and most picturesque views in the United Kingdom, embracing twelve different counties, can be obtained.

The town consists of Great and Little Malvern, which are about three miles apart. The picturesqueness of the site and surroundings of Malvern have been celebrated in prose and verse by Byron, Walpole, Southey, Browning, and Macaulay.

The Malvern air is dry and bracing, the climate tonic and stimulating, and the temperature equable. The drinking-water is of absolute purity and softness. The death-rate is low, being only 18.85 per 1,000. The sanitary arrangements are based on the best scientific principles. Over fifty thousand persons visit this spa during the season, which lasts from May to October.

ACCESS.—Malvern is one hundred and twenty-nine miles from London, and can be reached in about three hours by rail.

ANALYSIS.—The Malvern waters are faintly alkaline and earthy. Its brine baths are famous. The two springs of Malvern are St. Anne's and the Holy Well.

INDICATIONS.—The waters and saline baths of Malvern find their chief employment in cases of rheumatic gout and rheumatism, and their various sequelæ and complications; also in scrofulous disorders, neuralgia, sciatica, lumbago, etc.; swellings of the joints, contractions and anchylosis, paralysis, morbus Brightii, bronchial affections and chest complaints, skin diseases, old wounds, and ulcerations. *Edmund C. Wendt.*

MARGATE. One of the best known and most popular seaside resorts in England. Margate was once fashionable, but Ramsgate has outstripped this city by the sea in

that particular. Margate is in Kent. It begins in a valley and stretches up the slope of a hill. It has a famous pier, and in many other respects resembles our own Coney Island. Though quite open and exposed to trying winds, Margate is a healthy place, and the air there is remarkably keen and bracing. The famous Clifton baths, formed out of a cliff, are one of the main attractions of the beach, which is a fine sandy one. Margate is only two hours by rail from London, and about four hours by river steamer. Dr. Yeo speaks of Margate as follows ("Climate and Health Resorts"):

"Although often associated in men's minds with the neighboring resorts on the south coast, it must not be forgotten, in estimating the special qualities of the climate of Margate, that its aspect is not to the south, nor to the east, but to the north or northeast. Whoever will take the trouble to look at a map of this part of the coast of the Isle of Thanet will see that Margate has a decidedly northerly or northeasterly aspect. In this respect it differs entirely from the neighboring coast town of Ramsgate, which is so placed in an indentation of the coastline as to look southeast. From this difference of aspect it not infrequently happens that the local weather differs considerably in these two places, only a few miles apart, for a storm may be raging at Margate which is scarcely felt at Ramsgate. It happens also from this northerly or northeastely aspect of Margate that during the prevalence of the northeasterly winds of spring it is one of the very few conveniently accessible seaside resorts where, during that season, pure sea-air can be obtained. For the prevailing northeast winds blow directly over the North Sea and the northern portion of the British Channel on to Margate and the line of coast of which it forms a part, whereas during the same season the prevailing winds at the resorts on the southern coast are land winds and blow off the land out to sea, driving off, as it were, the sea air —hence, I take it, the great value which Margate air is known to possess in scrofulous affections.

"It has a chalk subsoil, and the ground quickly becomes dry after rain. The water supply is abundant and pure.

"The best residential part of the town is on the Cliff, where the Cliftonville Hotel stands; but the cheaper hotels and lodging-houses are on the lower ground, near the harbor and pier.

"The drainage of the higher ground is better than that of the lower level, which is not all that could be wished.

"Margate is too windy for cases of chest disease, except in the summer months, but it is especially beneficial to cases of scrofulous disease in children and to those of convalescence after surgical operations. This fact has led to the establishment there of that excellent institution, 'The Royal Sea-bathing Infirmary, or Royal National Hospital for Scrofula.'

"The air of Margate is excellent for promoting the progress of slowly healing wounds and ulcers, and it is valuable in cases of debility from inherited feebleness of constitution. It is also said, from its dryness, to be good for rheumatism.

"Its autumn climate is often very fine. In November, when London is foggy and the country damp, Margate rejoices in a clear, bright, and dry atmosphere.

"Margate is celebrated for its sands, which are very extensive, owing to the shallowness of the water. They are therefore the delight of children and those who do not care for a plunge into the deeper sea."

Edmund C. Wendt.

MARTIGNY-LES-BAINS. A spa in the Vosges Mountains, France, which has recently acquired an excellent reputation.

LOCATION.—Martigny is a village situated in a pleasant valley surrounded by wooded slopes. It is not far from the spas of Contrexéville, Bourbonne-les-Bains, and Vittel. Although its growing reputation as a watering-place is of recent origin, the place itself is said to date back to the times of the Druids, and there are seen to this day remains of undoubted Celtic origin.

The two principal springs of Martigny supply a chalybeate water rich in lithia. The waters are cold, clear, and slightly astringent to the taste. The climate is pleasant and bracing.

ACCESS.—Martigny-les-Bains (not to be confounded with Martigny in Switzerland) is a station on the Eastern Railway of France. It lies on the road from Contrexéville to Bourbonne-les-Bains.

ANALYSIS.—According to Wilm, one thousand parts contain:

	Parts.
Bicarbonates of lime, of magnesia, and of iron	0.3918
Sulphates of lime, of magnesia, and of lithia	0.8641
Chloride of magnesium	0.0071
Silicates of magnesia, of soda, and of potash	0.1383
Silica	0.0018
Organic matter and loss	0.0250
Total	2.3281

The more complete analysis of M. Jacquemin is as follows: One thousand parts contain:

According to Mr. Wolff ("The Watering-places of the Vosges") there is now a large new hotel with good appointments, which includes the thermal establishment. But although baths are much used "the main use of the water is for drinking. The hours are the same as at Contrexéville and Vittel, and so is the number of glasses taken, generally from eight to ten. There are grounds adjoining, covering something like twenty-five acres, and very prettily laid out. One very useful feature is the large covered *Promenoir*, in which are housed the two springs, and which affords shelter alike for walking after drinking, and for pretty free exercise in wet weather."

The older chalybeate spring is not much used now, and lies outside of the village.

INDICATIONS.—The lithia springs of Martigny are employed for the relief of gout, gravel, diseases of the bladder, hepatic congestion, and the various manifestations of the uric-acid diathesis. But dyspepsia, anæmia, and chlorosis, gastralgia, diabetes, and some forms of rheumatism and neuralgia are also said to be treated with advantage there. Those in search of a quiet watering-place, devoid of all the excitements of fashionable spa life, will find comforts that they will appreciate, amid surroundings that are interesting and agreeable at Martigny.

ACCOMMODATION.—In addition to the large modern hotel already mentioned there are a number of unpretentious establishments, with fairly neat and clean rooms and a modest bill of fare at decidedly reasonable rates.

Edmund C. Wendt.

MASSAGE. PHYSIOLOGICAL.—Experience has taught us that massage is a powerful tonic to the muscular system. But Professor Maggiora, of the University of Turin, has recently demonstrated this much more fully by a series of careful and pretty experiments, showing the rapidly restorative effects of massage upon muscles weakened from various causes (*Archives Italiennes de Biologie*, tome xvi., 1891).

1. The action of massage upon muscles in a state of repose was first studied. For this purpose the fatigue curves of the right and left middle fingers in voluntary flexion with a weight of three kilos (6.6 pounds) every two seconds were taken at 8 and 11 A.M., at 2 and 5 P.M., and the following day the fatigue curves of the same muscles, with the same weight and rhythm, were taken at the same times of day after massage for three minutes.* The average result showed that the muscles did almost twice as much work after massage as they did before. The average for the left middle finger was 4,252 kilos without massage; after massage, 8,019 kilos before extreme fatigue prevented further contractions. The right medius behaved similarly. Another series of experiments was made in which the same muscles were fatigued by the electric current applied to them or to the median nerve, and the same results were obtained as in the previous experiments, and showed that it takes much longer to fatigue muscles by electrical irritation after massage than before.

2. The next experiments were undertaken in order to ascertain whether the beneficial effects of mixed massage (friction, percussion, and kneading) increased in proportion to its duration. At 8 A.M. the normal fatigue curves were taken, then every two and a quarter hours after this they were also taken, having been preceded by two, five, ten, and fifteen minutes of massage of the right and left middle fingers. Ten tracings were thus obtained, and the result showed that five minutes of massage produced almost all the useful effect possible. When the massage was continued longer, for ten and fifteen minutes there were slight variations in the amount of work shown, above and below that after five minutes. The same results were obtained when electrical irritations were used to fatigue the muscles or applied through the median nerve.

3. The third series of experiments were employed with a view to determine the effects of the main procedures of massage—friction, percussion, and *pétrissage*. The methods were as before: first the normal fatigue curve was taken, then every two hours during the day fatigue tracings were taken after five minutes of friction, after five minutes of percussion, and after five minutes of *pétrissage* or kneading, and finally after five minutes of these three manœuvres alternating. There was little difference in the amount of work that could be done after five minutes of friction as compared with that after five minutes of percussion. There was a great increase in the force and duration of the contractions after *pétrissage*, but the best effects were obtained after an alternation of all three. Like results followed when the contractions were produced by electricity, and these three procedures of massage employed separately and alternately.

4. The effect of massage upon muscles weakened by fasting was such as to restore them temporarily to a normal condition, so that they gave tracings of fatigue equal to normal tracings not preceded by fasting. The same result followed when the electrical current was applied either directly to the muscles or to the nerve supplying them in place of voluntary contractions.

5. The effect of massage upon muscles fatigued in an indirect manner, or as the result of general fatigue, was also studied. After a walk of ten miles, Professor Maggiora took tracings of voluntary flexion of his right and left middle fingers. The amount of work of which they were capable was only about one-fourth of what they could do when there was no general fatigue. After massage for ten minutes they did nearly a normal amount of work, which, of course, was temporary. It has been found that the muscles of the fingers, fatigued in the manner mentioned by Professor Maggiora, by contractions with three kilos every two seconds, required two hours' rest in order that they might produce normal tracings of fatigue. (The massage was applied in this instance half an hour after the fatigue tracing was taken, so that making allowance for this extra work the inference would be fair that ten minutes of massage brought about more recuperation than two hours of rest. When there was no general fatigue, five minutes of massage to the finger would then equal two hours of rest, as in the other experiments.—D. G.)

6. After the loss of a night's sleep the fatigue curve was found to be very small, about one-fourth normal, but after ten minutes of massage it was temporarily restored to a natural curve, a result that was not obtained by nourishment nor by nerve tonics. In fatigue of muscles from fasting, rest alone will not restore them, and in muscular fatigue from wakefulness, food alone affords no appreciable relief.

7. The effect of massage upon muscles weakened by excessive intellectual work was also noted. After the final examination of twenty students, which took five hours, Professor Maggiora was much exhausted, and then took fatigue tracings of both middle fingers. These represented only one-fifth of a normal amount of work. Half an hour later, after ten minutes of massage, the amount of work was little less than natural, and probably would have been natural but for the extra work half an hour before.

8. After a slight attack of fever of ten hours' duration, the muscles were weak the whole of the following day. The influence of massage upon the flexors of the fingers increased their aptitude for work so that they gave a tracing of fatigue nearly normal.

9. Professor Maggiora showed that anæmia of a few minutes produced phenomena in muscles similar to fatigue. His brachial artery was compressed for three minutes, and a fatigue tracing was taken and found to be very small. Two hours later the brachial artery was again compressed for three minutes, and at the same time the forearm was subjected to mixed massage. Then another tracing was taken while the anæmia was kept up, and it was less than the previous one, showing that massage has no effect upon muscles when their blood-supply is shut off.

In comparing this last experiment with the preceding ones, it is evident that the effect of massage consists essentially in reawakening the phenomena of the local circulation, in bringing to the muscles a greater quantity of material necessary for their contraction, and in removing the retrograde products of muscular work.

Muscular Rheumatism almost invariably yields quickly to massage, and the result shows a fivefold influence: 1. Thermal: From equalized and increased circulation and warmth imparted by the hands of the manipulator. 2. Electrical: The muscles contract much more vigorously and agreeably to a faradic current after massage in these cases than before. 3. Neural: Pain disappears, which is brought about by, 4, the mechanical changes produced by massage, which dispels the muscular rigidity and the partial and irregular contractions of the muscular fasciculi, breaks up minute adhesions between muscular fibres, and thus restores flexibility and suppleness to the muscles, and removes pressure and pulling from terminal nerve filaments. Kühne has shown that the contractile substance of muscle is semi-fluid. The pathology of muscular rheumatism coming on suddenly is considered by Professor Busch to be a partial coagulation of the contractile muscular substance. The difference in the firmness of muscles lies not so much in the muscular substance as in the fascia that surrounds it. Where the fascia is thick the muscles seem hard; where thin, the reverse. Ludwig has shown the fascia to be a pump-like arrangement by which lymph is sucked out of the muscles and propelled onward into the lymphatics. Between the two layers of fascia are lymph spaces terminating in lymphatics. When the muscles contract, the inner layer is pressed against the outer and forces the fluid onward into the lymphatic vessels. When the muscles relax the inner layer falls away from the outer, and the lymph finds its way into it. Muscular contraction thus favors the removal of waste products. When muscles cannot contract without pain, as in muscular rheumatism, massage will more than make up for

* The ergograph of Professor Morse was used to take the muscular curves.

the loss of contraction. The intermittent pressure of massage has been demonstrated to increase the flow of lymph in a remarkable manner (see my "Treatise on Massage," pp. 72–75). In this connection a very practical hint is afforded us by those adhesions of the pleura which are frequently loosened by the rubbing together of the two membranes in respiration. 5. As to the chemical influence of massage in muscular rheumatism: It is pretty generally conceded that when a muscle or joint is impaired from fatigue, cold, injury, or rheumatism in the system, a deposit of uric acid takes place at the affected part. Therefore, when this gets well under massage, it may be reasonably inferred that the uric acid, or other *materies morbi*, has been got rid of. Further observations in this direction would be desirable.

I think that massage may be of some value in the diagnosis of doubtful cases of muscular rheumatism from neuritis. As ordinarily understood, muscular rheumatism is distinguished by rigidity of muscle, pain on motion, and ease when at rest. The immediate effect of massage in such is apt to be painful, but speedy relief follows. But there are many cases of what, I think, are erroneously called "muscular rheumatism," where the patients are much more comfortable when up and moving about, in which there is no perceptible muscular rigidity, but, on the contrary, there may be some flabbiness and slight atrophy of muscle, affecting either a single group of muscles or the same groups on each side of the body, and accompanied with some stiffness of motion, and in which pain is much aggravated after the patient has been warm and at rest in bed for some hours. In all probability these are cases of neuritis of the terminal nerve filaments supplying muscle, and the occasional appearance of neuritis affecting a distinct nerve-trunk in such cases would strengthen such a view. But be they what they may, the relief afforded by judicious massage is great and immediate, but not so lasting as in the previous class of cases. They quickly lose nearly all the comfort felt during massage, and it takes long to benefit them; thus in every particular differing from what we have hitherto understood by muscular rheumatism. The recent epidemics of influenza or grippe left a legacy of these neuro-muscular disturbances.

Pleuritic Effusions.—Ten cases of primary pleuritic exudations have been treated with massage of the chest by Dr. Poliakow (*Wien. Med. Presse*). Seven of these were purely serous, three sero-fibrinous. The manipulations were made in the direction of the lymphatics of the affected region. The treatment was begun with light stroking and soon brisk, deep massage was used, and this was followed by percussion, all occupying from ten to twenty minutes daily. The exudations disappeared in from eight to twenty days, and the other symptoms in from nine to thirty-five days. The chest pains were relieved, the muscles invigorated, and the respiratory movements increased in volume, and thus a marked influence on the absorption of the exudation and the distention of the compressed lung was obtained. Dr. Emil Schlegel has also reported several cases of pleuritic effusion where the absorption of the fluid seemed to be accelerated by means of massage. This was used in the form of percussion only, with the ulnar border of the hand striking at the rate of two blows a second, or six hundred in five minutes, which made a sitting, and two of these were given daily. Dr. Schlegel's enthusiasm carries him a little too far, for he believes that percussion might be quite as useful for promoting absorption in the intra-cranial cavity, the spinal canal, etc., forgetting that the blows would have to be so hard, in order to be effectual, that the patient would have reason to object.

Neuritis.—Massage is becoming more generally accepted as one of the proper measures to employ in cases of neuritis. In the early stages it may be used to push the blood out of the distended vessels and to create a free circulation in the adjacent tissues; in the later, to promote absorption of inflammatory products by spreading these over greater space, and for the relief of minute adhesions and thickening of the nerve-sheath. But the sentiment largely prevails throughout the profession that cases of fully developed neuritis ought not to have massage. Nevertheless, testimony is accumulating that even here it may be beneficial. I have recently had two cases of acute neuritis of the sciatic nerve in previously healthy people, in which the result was all that could be desired. In one, massage was used in conjunction with galvanism and tonics; in the other both medical and electrical means had been exhausted. It was the patient's third attack, the first having lasted for three months, then, after an interval of several years, came the second attack, which lasted for six months, and at this rate of increase we feared that the patient was in for a year of it with his third attack, which appeared several years after the second. But under massage alone the whole aspect of the case was speedily changed, and in the course of a few weeks the patient resumed his arduous professional duties.

Dr. A. Symons Eccles, of London, has reported in detail three cases of highly acute neuritis[1] of the sciatic nerve in previously well people, which he treated successfully with rest, position, and massage (*effleurage*, kneading, and percussion). In the intervals between the massage, the leg was suspended in a Salter's swing. It was contrary to all expectation that percussion could be used to advantage in such cases, but experience proved the value of it. In six other cases of sciatica that occurred in patients of an anæmic type the sciatic affection was evidently a concomitant of the general condition. In these general massage of the body, with frequent meals and the avoidance of all pressure upon the nerve-trunk, were kept up from four to ten weeks, with the result that not only was the sciatic pain removed but the patients all improved in appetite, weight, and strength.

Local Neurasthenia.—Neurasthenia, as I understand it, may be either general or local, affecting the nerves or nerve-cells of all or any part of the cerebro-spinal or sympathetic system. Its manifestations are those of exhaustion or too easy exhaustibility of nerve-force; and its pathology, malnutrition of the nerve-cells involved, with concomitant instability of their circulation in the form of anæmia or hyperæmia, or alternations of these. It predisposes to, it accompanies, it results from disease; the nervous shock and the tedious recovery from injuries point to other sources, and it may be caused by overwork, worry, or sheer laziness. The agreeable fatigue after a satisfactory day's work that insures sound sleep may be regarded as a healthy form of neurasthenia, if the Hibernianism may be pardoned.

It is a matter of common observation that those who are compelled to hard manual labor seldom suffer from nervous prostration, and among the more fortunate who may be predisposed to neurasthenia, those who are deeply interested in some hobby or occupation that keeps mind and body active, have found the best means of prophylaxis. The same means that serve for its prevention also supply us with a clue to one of the most valuable agents that can be employed for its relief or recovery. Exercise keeps the circulation active, but requires effort of brain, spinal cord, and nerves, as well as muscles, at a time when our object may be to afford rest to one or all of these parts of an overtaxed nervous system. Massage supplies this want, and will keep the circulation going with a minimum or no expenditure of nerve-force from the patient, and deep massage without friction will lessen the beats of the heart and afford it rest also. Nay, more, for it is getting to be the fashion not only among the laity, but also with some physicians, to say that massage imparts energy to the patient, though I confess I do not exactly understand what this means. Certainly many who submit to massage feel much more vigorous, light, and supple after even the first application than they did before it. But may not this rather be owing to the rousing of their latent energies and restoring the equilibrium of their forces by facilitating the circulation of blood and the flow of lymph and the transmission of nerve-force?

I have previously stated elsewhere that in cerebral exhaustion the relative value of massage was almost *nil*, and that out-of-door exercise was of paramount impor-

tance; but I have since found reason to modify this in favor of more massage and less exercise. In such cases, massage of the head alone daily, or every other day, is better than applying it all over the patient, unless there be a rare idiosyncrasy that will not allow the head to be manipulated.

There are people, not a few, who, when using their brains, suffer from uneasy sensations in the lumbar or dorsal region, and these discomforts continue after the cessation of study, causing wakefulness. Generally, there is also some spinal irritation in the region affected. In such cases massage of the back alone will often induce sound sleep, and next day the patient feels inspired with faith, hope, and courage, in place of doubt, dread, and fear of meeting appointments. With these cases a much more marked effect is produced by local than by general massage, except when the tenderness of the muscles and spinal irritation are extreme, unfitting them for every kind of work, and then the massage should be general, omitting the back at the first *séances*, but gradually approaching it at subsequent ones.

If space permitted I could give details of cases which would seem to justify the following conclusions:

1. That massage induces sleep.

2. That even when massage is applied in the forenoon its soporific effects may not disappear before bedtime, though in general the later in the day massage is used for promoting sleep the better.

3. Disagreeable feelings of drowsiness and languor do not necessarily intervene between massage in the forenoon and sound sleep at bedtime. Aptitude for rest or work generally follows massage. The mind is clearer, the mental faculties work easier and longer, the muscles are more supple, and do not tire so soon.

4. When people are wakeful after massage they may not be restless nor feel the loss of sleep on the following day. Generally they do not.

5. Spinal irritation is relieved or disappears under massage.

6. For local neurasthenia there is no need of general massage unless the whole system be secondarily affected.

7. When affections have come to a standstill under massage, improvement may yet go on after massage has been discontinued.

8. For improving the nutrition of nerves and muscles, restoring natural sensation and motion, massage may succeed when other means have failed.

9. Deep massage without friction has proved of more value in my hands than all other forms of massage put together.

10. Massage can be overdone, producing opposite effects from a moderate application.

11. Besides massage, carefully graduated exercises at regular times are valuable accessories in the restoration of motion.

12. Massage is not the only means of treatment for neurasthenia. Its selection is usually decided upon after the failure or exhaustion of every other means; in the same manner that the shrewd old divine decided that it was not wise to let the devil have all the good tunes to himself.

Diabetes.—Massage under the water, or *douche-massage*, constitutes the peculiar mode of administering the warm hydro-sulphuretted water of Aix-les-Bains, where it has been in use from time immemorial. The water is too feebly mineralized to be rationally employed in any other way than externally, which is thought to favor the absorption of sulphuretted hydrogen by the skin.

Dr. H. Forestier, physician at Aix-les-Bains, has employed this treatment in seven cases of saccharine diabetes in fat people, with the interesting result that there was an enormous decrease of the glycosuria without the intervention of any change in the alimentary regimen or the administration of any medicine.[2] The patients lived *à la table d'hôte*, eating a mixed diet of meats, sweets, fruits, and amylaceous substances. They followed their ordinary habits of exercise. The *douche-massage* was used with the patients seated or lying, while two *masseurs* occupied themselves, the one with the limbs, the other with the trunk, adroitly directing a jet from a nozzle under the arm, douching with both hands and *masséing* at the same time. This occupied ten or fifteen minutes. The temperature of the water was from 37° to 40° C. (98.6° to 104° F.).

The patients thus treated were classified as belonging to the clinical form of diabetes known as *diabète gras* of Lancereaux, or the slow diabetes of the English. All seven presented very similar features—age fifty to sixty years—*embonpoint* or confirmed obesity, extreme thirst, passage of excessive quantities of urine, and great muscular fatigue on slight exertion. These symptoms were overshadowed in four of the cases by arthropathies, and in two by neuralgia which had been mistaken for chronic rheumatism; and in one of them this diabetic neuralgia seemed like that of tabes, affecting the crural and sciatic nerves. In those patients with a large quantity of sugar in their urine, as well as in those with a small quantity, there resulted the same modification in the excretion of urea. Before the *douche-massage* this was less than normal, but under this treatment it increased, thus demonstrating increased oxidation and acceleration of retarded nutrition. The decrease in the sugar was great. In the first case, from 24 grammes in twenty-four hours to 1⅘ grain after the twentieth massage, in twenty days. In the second case, from 117 grammes in twenty-four hours to 66 grains after the twenty-fifth massage, in twenty-five days. In the third, from 87 grammes to 18 grammes after twenty massages, in twenty-two days. In the fourth, from 319 grammes to 101 grammes after nineteen massages. In the fifth, from 42 grammes to 5 grammes after twenty massages. In the sixth, from 30¾ grammes to 11⅔ grammes after twenty massages, in twenty-four days. In the seventh, from 291 grammes to 80 grammes after twelve massages.

The quantity of urine also decreased. The general condition of the patients improved, appetite and sleep were also made better. The pain and stiffness of those whose joints were thus affected were greatly benefited, but the neuralgia affecting the crural and sciatic nerves in one patient was still troublesome, though his general condition had become excellent.

The *douche-massage* would thus seem to be one of the most powerful means of hygienic therapeutics for fat diabetics, and can be used at the same time with other treatment, such as the internal use of the waters of Carlsbad and Vichy and Brides. But these are probably better adapted for diabetics with hepatic troubles and large livers, whereas the hygienic treatment of the *douche-massage* is rather indicated for cases where there is no appreciable trouble of the liver and where the general condition alone seems to be at fault. As to the duration of improvement after massage, but little is said except in two cases: in the one that had 319 grammes of sugar in twenty-four hours, after nineteen massages, this was 101 grammes; and at the end of eight months at home, on modified diet, this had still further decreased to 2 grammes. The following year he went to Vichy, and two months after he had left there the urine had 53 grammes every twenty-four hours. In another case that had been at Vichy for several years, the glycosuria had always increased to the same degree in the intervals between the seasons. After twenty massages, it decreased from 42 to 5 grammes, but how long it remained thus we are not told. The results must probably have been more favorable if the diet had been restricted, but in order not to obscure the results of the *douche-massage*, a full mixed diet was allowed. This might be a good course to pursue when the physician is obliged to use milder treatment than that of special diet, in order not to discourage the patient.

Professor Finkler has tried general muscle-kneading in fourteen cases of diabetes. The patients were at first masséed daily, and later, morning and evening for twenty minutes, over all the muscles of their bodies. The diet at the same time was mixed. A few of the patients were confined to bed, others were able to go about, and some did severe manual labor. The result, on the whole, was favorable, as shown by decrease in the quantity of urine

and of the sugar contained in the same, diminution of thirst, return of perspiration, and increase of body weight. After three months' treatment of one patient the sugar entirely disappeared from the urine, and this remained absent for three months after the last massage, then the sugar reappeared (Schmidt's "Jahrbücher," Bds. 2 and 3, p. 318).

As there was no external application used with the massage in Professor Finkler's cases, the result would probably have been as good in Dr. Forestier's cases without the douching with the waters of Aix.

Intermittent Fever.—Dr. Feroykövy, in the *Internationale klinische Rundschau*, states that in the Austrian army about one thousand soldiers were treated for intermittent fever annually. One of these cases was that of a soldier in whom neither the hot nor the cold stage was observed. He suffered only from severe vomiting, which quinine alone could check. Another case was characterized by severe sciatica. On one occasion when no quinine could be obtained, Dr. Feroykövy ordered these patients to be rubbed on the back with simple ointment. This was done twice in one day, and at the visit next day he found that the attack of fever which had previously occurred regularly had not made its appearance. The massage was later carried out in seventy patients suffering from intermittent fever without the use of quinine, and in sixty cases of quotidian fever the attack did not recur any more, but in ten cases of tertian fever massage had no effect. The same treatment was then tried in over one hundred cases, and in the "vast majority" the result was satisfactory.

Massage of the Heart.—Massage of the heart is very much overestimated. General massage is of great aid to the peripheral circulation, lessens the work of the heart, tranquillizes the nervous system, and induces sleep, even in the worst cases of heart disease. In a recent work Oertel places altogether too much importance upon the mechanical effect of massage of the heart over the chest-walls. In order that massage might act upon the heart in the same way that it does upon the muscles of the extremities (which he claims), it would be necessary to remove the chest-walls, a procedure that would hardly be justifiable. While the patient is standing he directs that gliding pressure should be made upon the chest-walls, downward and inward from the axillary line, the benefits of which he states are not only referable to its influence in perfecting expiration, but also to the direct pressure upon the heart, influencing its nutrition precisely as massage benefits the muscles of the extremities. It is indicated, he says:

1. When the heart-muscle is weak from deficient nutrition, anæmia, or corpulence.

2. When the arterial system is imperfectly filled and there is passive congestion as a result of insufficiency of the myocardium.

3. When there are valvular lesions or obstruction to the circulation, the pressure of tumors, or constriction of the pulmonary orifice. Emphysema and curvature of the spine increase the demands of the heart.

4. As an accompaniment of treatment of the heart by mountain climbing.

It is contra-indicated in acute or recurring endocarditis or pericarditis, in acute or subacute myocarditis, the result of sclerosis of the coronary arteries, and in general arterio-sclerosis.

But the great authority in this matter, according to Dr. Sarah E. Post, is the renowned pugilist, John L. Sullivan, of whom she says: "It is idle to fight with facts when a man like the great Sullivan insists upon being rubbed down and not up. . . . Horses, too, are rubbed down and not up" (*Massage Primer*, p. 27). The horses know as much about this as Sullivan. A moment's reflection will show that rubbing down would tend to produce engorgement of the venous and lymphatic systems.

Myxœdema.—I had never heard of massage being used in myxœdema prior to May, 1885, when Professor Robert T. Edes sent me a case. It was that of a man fifty-six years of age, who had suffered from the usual symptoms of myxœdema for four years. The result of a course of general massage every other day was most satisfactory. The boggy, brawny, waxy condition of the tissues gave place to suppleness and elasticity, freedom of motion, improved mental tone, and better hearing. Seven years have elapsed and the improvement has continued. Since then several cases have been reported much improved or cured by means of massage and hypodermic injections of an extract of the thyroid gland of a sheep. A most interesting case of this kind has recently been published in the *British Medical Journal* by Dr. Wallace Beaty. The patient, a lady forty-five years of age, had for five or six years become more and more easily tired, speech had become slow, memory impaired, temper irritable, walking difficult, constipation increased, susceptible to cold, etc. Her face was swollen, waxy-looking, and anæmic; lips and alæ nasi thickened, nose broadened, hair thin; hands and feet, arms and legs were enlarged and clumsy. No trace of the thyroid gland could be made out. Examination of the blood showed hæmoglobin to be seventy per cent. of the normal. Five weeks of massage brought some improvement, and then hypodermic injections of an extract of sheep thyroid gland were also used, and more rapid improvement followed. The patient was under this treatment for twelve weeks, continually improving. After treatment was discontinued she steadily progressed. "Now she is practically cured. The face looks natural, the skin of the face is no longer swollen, the lips and tongue are of natural size, the speech is rapid and easy, the hands are no longer clumsy, she can give a hearty and firm shake-hands, her rings are loose and easily removable, her movements are active, her hair, which had become thin, is now growing thickly; her memory has returned, menstruation, which was absent, is natural."

Massage of the Abdomen for Indigestion.—In dilatation of the stomach and chronic dyspepsia massage has proved of benefit, the distressing symptoms disappearing and the patients gaining flesh and strength. It should be applied as much as possible over the stomach, working from the left side upward and inward under the false ribs, so as to empty the stomach of its contents while stimulating the contractility of its muscular walls. The effect of gravity causes the food to lodge in the most dependent portion, in the greater curvature, and it needs to be pushed along toward the pylorus, at the same time that its peristaltic action is being increased. The whole abdomen should be *masséed* at the same sitting, as the bowels are also usually sluggish in these cases. Rubens Hirschberg, of Odessa, reports many cases of this kind which he relieved or cured by means of massage, and lays special stress on the fact that massage has an ultimate chemical influence in causing the disappearance of sour, burning eructations, foul breath, and bad taste in the mouth, as well as of sensations of weight and fulness, which would indicate an improved state of the gastric juice and better contractions of the stomach. I have witnessed the same result in several cases under my care. Hirschberg invariably found in these cases what I have seldom met with, that massage of the abdomen for thirty minutes had a decidedly diuretic effect, the daily quantity of urine in some being increased to three times the usual quantity, without any other inconvenience save that of frequent micturition. When massage was discontinued the urine fell to its former quantity. The increase of urine probably depends upon more active absorption of fluids from the digestive tract, increased blood-pressure, and stimulation of the splanchnic and pneumo-gastric nerves below the diaphragm, caused by massage. Contra-indications to the use of massage over the stomach or bowels would be symptoms of cancer or ulcer, acute or febrile states, and a suspicion of a tendency to hemorrhage. If cicatricial contraction of the pyloric orifice existed, massage might increase the dilatation, for the walls of the stomach would then in all probability yield more readily than the cicatrix.

Salol serves a useful purpose in showing us when the contents of the stomach pass into the small intestine. Insoluble in the gastric juice, it is decomposed into its

two constituents, salicylic acid and carbolic acid, in the small intestine, where it is subject to the action of the pancreatic juice, which renders it soluble and easy of absorption. Soon after absorption into the circulation it passes through the kidneys into the urine as salicyluric acid and sulpho-carbolic acid, its presence being shown by the production of a red-violet precipitate when the urine, after acidulation with hydrochloric acid and shaking with ether, is tested with a solution of perchloride of iron. Professor Ewald tied the pylorus of a number of dogs, then gave them large quantities of salol, without obtaining the reaction of this in the urine. Dr. Sahli found that acute catarrhal conditions, as well as chronic dilatation of the stomach, delayed the decomposition and absorption of salol. The experiments of Professor Ewald and Dr. Eccles agree in that they found, in most cases under natural conditions without massage, that salol could be detected in the urine in forty-five minutes after its administration; but after massage upon the abdomen for fifteen minutes the reaction of salol was obtained in thirty minutes.

In two obstinate cases the addition of general massage had a more favorable effect in hastening the absorption of salol than did massage of the abdomen alone.

After the administration of one gramme of salol to people suffering from chronic dyspepsia, Hirschberg, Brunner, and Huber found that it required from two hours to two hours and a half before the reaction of salol could be detected in the urine. But after a walk of fifteen minutes or gymnastic exercises for ten minutes, the reaction was obtained in one hour and five minutes. Similar results were obtained from faradization, but massage proved more efficacious than any other means. Hopadzë has made a series of observations showing that massage of the abdomen for ten minutes lessens the sojourn of the food in the stomach from fifteen to seventy-five minutes. He also made other observations upon healthy people, proving that the nitrogenous metamorphosis in four persons to whom he gave daily massage for twenty-five minutes invariably increased and lasted for seven days after a week of massage. The assimilation of the nitrogenous substances of the food increased in all the cases, and lasted during the week following the week of massage; but during the week of massage one gained in weight, two lost, and one was unchanged. The results obtained by Zabludowski were similar.

Relaxation of Ligaments is often erroneously diagnosticated after the improvement of a joint from the acute symptoms of disease or injury. It is much more frequently the case that the muscles moving it are atrophied and relaxed in consequence of the necessitated disuse, which thus allows too great traction upon its ligaments. Massage, carefully regulated movements, and faradization will restore the nutrition and tone of such muscles, and if the disturbance of the joint has disappeared, the limb can thus be got well. In three cases of this kind I had the pleasure of training the affected muscles as mentioned, so that from being totally unable to extend the affected leg at all, in a few weeks they could hold it fully and voluntarily extended for seven, nine, and ten minutes, respectively. The first of these was a stout elderly lady, who still had the remains of an old synovitis when she began this treatment, under which she fully recovered. The second was a gentleman of sixty-three years, who had developed a rheumatoid arthritis of his left knee in consequence of an injury, and though the peri-articular thickening disappeared, and the quadriceps extensor muscles improved so that he could hold the leg extended for nine minutes, yet grating of the articular surfaces remained, and locomotion was much impaired. The third was a long-levered, awkward woman, who had for many years suffered from relaxation of the quadriceps extensor to such an extent that it allowed the patella to slip externally without the power of voluntary or involuntary replacement, causing her many bad falls. When she had gained strength sufficient to hold the leg extended for ten minutes, she had correspondingly good use of the limb, but for security I still made her wear a few turns of roller bandage to keep the patella *in situ*. Let any of our readers take his watch and try to hold his leg and thigh fully extended without support for one or two minutes, and he will appreciate what was accomplished in these cases.

Massage in Sprains and Fractures.—It is an encouraging sign that physicians and surgeons are beginning to use massage themselves in sprains. The orthodox treatment of absolute immobility alone in these cases has little else to support it than the dogmatism of centuries, from which it has been almost impossible for a surgeon to free himself unless he has been the unfortunate victim of a sprain and had it treated with massage. Supposing that anyone wanted to make a well joint stiff, to what more effectual means could he resort than first to give it a wrench or sprain, and then do it up in a fixed dressing, so that the resulting inflammation would have an opportunity to produce adhesion of the tissues? Precisely the same course of treatment is employed for the purpose of closing up a hole, namely, that of exciting adhesive inflammation, and unfortunately it sometimes closes the cavity of a joint also. In my "Treatise on Massage" will be found the method of applying massage in sprains, and its results in seven hundred cases, showing that they got well in one-third of the time that they do without it, and with less tendency to subsequent pain, weakness, and stiffness than when massage had not been employed. The earlier after a sprain massage is employed, the more speedily does recovery take place. But sprains are sometimes complicated with fractures near and into joints, and of late years massage and movements have been used in these cases with advantage over the ordinary methods. In intra- and para-articular fractures the French surgeons, MM. Championnière, Tripier, and Rafin, have found that immobilization is accompanied with danger, whereas massage acts well from the first and can be used with other means. Their experience has been confirmed by Professor Lauderer, Dr. Kendal Franks, and others. The dangers of immobilization are stiffness of the joints and atrophy of the muscles; and the anæmia of the muscles (ischæmia) caused by fixed dressings may be mistaken for neuritis. It has been demonstrated by Kraske that the application of a rubber bandage to the leg of a rabbit for six hours has produced *vitreous* (hyaline) degeneration of the muscles, from which they cannot recover, The advantages of massage are that it promotes absorption of effused products, prevents stiffness of the joints and atrophy of the muscles, and favors repair. It should be done once or twice daily in these cases.

M. Championnière found that massage relieved pain, as most observers do who know how to apply it, but M. Rafin states that its application was painful. The manner of employing it would probably account for the difference. This is not stated. I have elsewhere given full directions how painful, swollen, and tender tissues can be gradually approached without hurting by working first on the adjacent healthy parts. Good recoveries were obtained by both MM. Championnière and Rafin, in from one-half to two-thirds of the usual time. Those cases in which there was no displacement did well under massage, and passive motion without immobilization. Those in which there was displacement of the fracture had massage at first to hasten absorption, then a retentive dressing for the shortest time possible to make sure that the displacement would not return, and after this massage and passive motion for the restoration of mobility. As soon as consolidation had taken place it was found that motion was free and easy.

In an article in *L'Union Médicale* of February, 1889, on fracture of the fibula treated by massage and mobilization, M. Marévery summarizes his experience by saying that almost all of his patients treated in this way recovered the use of their limbs in less than nineteen days after the injury. This treatment he finds can be used only for certain fractures, such as those of the inferior extremity of the radius, and of the lower end of the fibula. He also made use of cold applications and the rubber bandage as well as massage from the first, and passive motion was given to the joints early.

Professor Lauderer applies a fixed dressing for four or five days at first. After this he removes it for a short time daily in order to give massage, and at the end of ten or twelve days consolidation is sufficiently advanced to lay aside the splint altogether. This plan of treatment he finds preferable to all others for transverse fracture of the patella, as it is safe and simple and gives good results, the patients going about freely in four or five weeks. He has employed it in ninety cases of simple fractures of various bones, including fracture of the olecranon, of the anatomical neck of the humerus of the thigh, etc.[3] Dr. Kendal Franks considers that certain fractures are well suited for massage, such as fractures of one of the bones of the leg or forearm when the other bone acts as a natural splint and prevents displacement; and transverse fractures of the humerus and forearm or leg. The temporary removal of the splints in these cases for massage is not attended with any risk.[4]

In transverse fracture of the patella, even where good union has been obtained either by immobilization or by suturing of the fragments, or by fixation of them with Malgaigne's hooks, the resulting stiffness of the knee-joint, atrophy of the quadriceps extensor muscles, and impaired motion may cast a shadow of gloom over the most careful treatment or the most skilful operation. But the lesson taught by the cases in which the fragments have remained widely separated, and yet accompanied by good motion, has not passed unheeded. Professor Tilanus, of Amsterdam, treats cases of fracture of the patella without immobilization, using instead compression, massage, and early movements of the joint, leaving consolidation to take care of itself, for union is by no means certain under the best of care. In this manner the effusion is quickly dispelled, atrophy and stiffness prevented. His patients were encouraged to walk after the first week. Of six cases that Professor Tilanus treated in this way, the patients could walk very well in fourteen days (according to his own statement); —Rafin treated one case in this manner and the patient could walk perfectly in forty-two days, experiencing only slight difficulty in descending stairs. The seat of the fracture could then be felt with difficulty, being marked only by a slight depression of the skin, and the leg could be flexed within two fingers' breadth of the thigh.

Dr. Wagner, a regimental surgeon of the Austrian army, states that he has obtained astouishingly good results in five cases of fracture of the patella which he treated with massage, passive and active movements, but without even the application of a bandage. His method is somewhat as follows: The patient is put to bed and the affected limb stretched on a simple inclined plane, or on an adjustable wooden splint, so that the heel is elevated. In the first three or four days an ice-bag is placed upon the swollen and painful knee. As early as the fourth day massage may be begun, not only over the entire extent of the quadriceps extensor muscles, but also over a large portion of the knee-joint. This is done daily and soon followed by passive movements. As soon as possible the patient himself begins to move the joint, and after fourteen or twenty days may attempt to walk on crutches, and in six weeks is usually able to walk without support. Should the fragments be widely separated, Wagner advises subcutaneous suture, but even here massage and exercise "cannot be begun too early." In fine, by means of massage and movements, the indications in every case are largely met. These are, the removal of the effusion so as to allow the fragments to come closer together, the favoring of repair and the formation of callus, the prevention of atrophy of the quadriceps extensor and the shrivelling of the capsule, and the early restoration of motion. It is needless to state that these manipulations should only be undertaken by some one having sufficient anatomical and surgical knowledge.

It is worthy of notice that the principal muscles of the quadriceps extensor that effect extension of the leg, are the vastus internus and vastus externus. The insertion of these on the lateral aspects of the patella extends much lower than is generally supposed, and affords leverage to extend the leg when a fragment of the patella is detached above their insertion. Rupture of the rectus femoris alone has little or no influence in hindering walking (after the immediate effect of the injury is recovered from). Dr. Kummer, of Geneva, and Dr. Kaufmann, of Zürich, and Mr. Page, of Newcastle-on-Tyne, have each performed total extirpation of the patella for disease of that bone without impairing the patient's gait or interfering with the movement of the knee-joint, when the latter was healthy. Slightly weakened power of extension of the leg was the only noticeable feature on close examination.[5]

After union of any solution of continuity, whether of bone, muscle, or nerve, massage and movements are in order, and even when repair is going on the mobility of the joints may be still better secured by altering the position of them at each dressing.

Contusions of Joints or Muscles are speedily relieved of pain, swelling, and stiffness when massage is applied from the first, and atrophy, which is so apt to follow even slight injuries of this kind and of sprains, is prevented. M. Castex has recently made a very interesting series of observations, both clinically and experimentally, on this subject (*Archives Générales de Médecine*, 1891-2). For the sake of comparison he purposely bruised corresponding muscles and joints of the same legs of various dogs, and to one limb he gave massage, and to the other none. The limb that was *masséed* quickly recovered, while the other remained swollen, sore, and stiff, and later there was atrophy of the muscles. His experiments were carefully watched by others, who did not know which leg was being *masséed*. Massage gave like good results when applied *immediately after* the reduction of dislocations in dogs, and in man also the results were very favorable when massage was used after the joint had been held in place for a few days.

M. Castex reaches the following conclusions, which are based upon both clinical and experimental observations:

In *simple contusions* of muscles massage rapidly dispels the various troubles, but principally the pain.

In *articular contusions* massage dispels the reflex muscular contractures and the pareses, and above all it prevents the rebellious muscular atrophies which are the most serious complication thereof.

Applied to sprains, it is remarkable by the rapidity of its good effects.

In *luxations* we ought to have recourse to it as soon as the reduction is assured, for it very speedily reduces the swelling, the ecchymoses, and the pain. It awakens the muscular fibres from that local stupor into which they have been plunged by the injury. It prevents atrophy and stiffness.

Applied to *juxta-articular* fractures, massage rapidly terminates pain and swelling. By this means a simple fracture of the inferior extremity of the radius without deformity is cured in fifteen days, whereas it would take forty days, at least, with plaster immobilization. If it is applied after the removal of the fixed dressing it renders the parts supple and dispels the œdema.

Massage has proved of little use against acquired muscular atrophies. It prevents them when applied early.

Histological Results. — The muscle injured and not *masséed*, under the microscope presented a *diffuse sclerosis* with hypertrophy of the connective tissue in its various parts, interstitial hemorrhages, engorgement of the blood-vessels, and hypertrophy of their external coat.

The muscle injured but *masséed* presented a normal histological aspect.

The blood-vessels are normal in the muscle *masséed*. In the muscle not *masséed* they show a hyperplasia of their external coat.

The nerve-filaments in the *masséed* muscle are normal; in the non-*masséed* muscle they present evidences of perineuritic and interstitial neuritis with compression of the nerve-tubes. The perineurium is at least three times as thick in the *non-masséed* side as it is in the *masséed* side. The lesion of the nerves is more marked than that of the vessels.

In brief, massage acts by deterging a part from the various injurious materials which have been poured into it as a result of injury, in bringing this part back to its normal condition, and in preventing the process of diffuse sclerosis which would result. Such is the positive explanation of massage, and it can only increase its credit.

INCONTINENCE OF URINE IN FEMALES.—Some of our readers may wonder why attention has not been given in this article to massage of the uterus and its *suburbs*. For information on this subject we would beg leave to refer them to my "Treatise on Massage," which has a chapter on "*Massage of the Uterus and its Surroundings*," which the New York *Medical Record* said was "worse than ignoranee," while the *Dublin Journal of Medical Science*, August, 1891, said of the same: "Those who objected so strongly a short time ago to the employment of massage in these regions, would do well to read this chapter and to bear in mind the author's observation, that 'Massage of the pelvic organs should be entrusted to those alone who have clean hands and a pure heart.'"

It is both novel and interesting that massage can be applied to relieve and cure incontinence of urine in females. Dr. W. S. Bagot, of the Rotunda Hospital, Dublin, has used it with complete success in a number of cases of this kind. His method is that of Brandt stripped of all unnecessary details. He introduces the index-finger of the left hand into the vagina (the rectum in children), slightly flexed and passed obliquely, so as to partially encircle the neck of the bladder. The right hand grasps the wrist so as to regulate the pressure used, and then the finger in the vagina or rectum is made to vibrate against the neck of the bladder, compressing it with moderate force against the pubes. This is done three or four times, and then the opposite side of the bladder is treated in the same way with the index-finger of the right hand. In this manner one patient, who had suffered for a year and a half from incontinence of urine, with a patulous urethra and slight prolapses of the anterior wall of the vagina, and abnormal distensibility of the perineum, was cured in twenty-nine days, and nine months later had no relapse.[1] Another patient, twenty-four years of age, who had suffered from nocturnal enuresis from childhood, was treated in this way every other day for five weeks, and thus got well. Another patient, forty years old, whose water had passed from her involuntarily for three years while walking, got well in three weeks under this treatment. Brandt and Boldt have also reported numerous successful cases treated in this way when other means had failed. A lady who had been treated by some of the most eminent German specialists by dilatation of the urethra, electricity, etc., for incontinence of urine of six years' duration, was cured by Brandt in eight days. In two cases of children, aged nine years, Boldt reported success after treatment of three weeks.

Dr. Sänger's method is also a sort of massage, and has been successfully used for incontinence of urine in females.[2] It consists in dilating the vesical sphincter with the patient in the dorsal position. The urethra is disinfected and a metallic female catheter is passed into the bladder a distance of from five to seven ctm., so that its point is on a level with the orifices of the ureters. The tip of the right index-finger being kept in the mouth of the catheter prevents the urine from flowing off, while the index- and middle-finger of the same hand steady the instrument. The index- and middle-fingers of the left hand are placed upon the catheter close to the urethral orifice, and with these the operator makes a springy and forcible pressure, at first downward and then toward both sides, alternately, so that the urethra becomes widely open and urine flows out by the side of the catheter. Thus the sphincter of the bladder and the muscularis of the urethra are strongly stretched. Further massage can also be done by a finger in the vagina or rectum pressing against the catheter. The stretchings are not very painful, but in sensitive people the urethra can be previously brushed with a ten per cent. solution of cocaine. Ten or twelve *séances* usually suffice. They should be twice daily at first, and later every other day. The stretching causes an irritation of the sphincter which makes it contract more strongly, both in a direct and reflex manner, and thus a certain degree of hypertrophy from work is set up. This method is not applicable when there is an abnormal dilatation of the neck of the bladder and of the urethra with incontinence.[6] *Douglas Graham.*

MASTOID ANATOMY, FROM THE SURGICAL STANDPOINT. From its revival, in the middle of this century, the operation of opening the mastoid process to evacuate pus, which had undergone an eclipse after its introduction by Petit (1750) and Jasser (1776), has been growing greatly in frequency and success. To this nothing has contributed more than the anatomical studies which have thrown increasing light upon the structure of the parts involved and pointed the way to avoidanee of the dangers which surround it. Now, the well-posted aurist feels that the field is as safe as any in surgery, that the indications for operation are as well defined, and that the serious or fatal results of timidity or neglect are as likely to be the subject of lay criticism as unlueky temerity would have been at an earlier epoch. The advances of pathology have cleared up many of the mysteries as to the causation of brain-abscess, septic thrombosis, and neck-abscess, formerly not recognized as aural in origin; and the progress of otological teaching and practice has done much to disseminate information and lead each medical man to call in the aid of a specialist when he feels unwilling to proceed unaided.

The earlier operations were usually either guided by the presence of a fistula or softened bone, or were done with a blind boldness that could not be often repeated without disaster; and the procedures described and commended were sometimes such as could rarely be safe. Because Kölpin bored a hole up and back of Von Berger's ear, where he was certain to enter the cranial cavity or the lateral sinus, the operation was discarded for a century. In like manner the real dangers of imperfect procedures and the magnified risks of those better planned have greatly retarded the due acceptance of the measure. Yet the wide experience of many men has demonstrated the value of operation for the saving of life, of hearing, or of time; since the fatality among the cases not operated upon is many times greater; the damage to the organ of hearing, when they survive, generally much more serious; and the treatment, though at times many months long after operation, is apt to extend over years without it. Only in cases where the indications are very doubtful can the over-cautious any longer claim that it is less dangerous for the competent surgeon to temporize than to explore; and as the knowledge is spread of the best rules as to when and how to operate, a still more brilliant showing will be made.

The mastoid process is a conoidal protuberance of the lower posterior portion of the temporal bone, forming the major part of the insertion of the sterno-mastoid muscle. It is developed from the outer part of the petro-mastoid and the lower posterior part of the squamous, and enlarges from an inconspicuous tubercle at birth to form the large process usually found in the adult. It is a response in part to the needs of the muscle inserted upon it, and shows an external development usually corresponding to the general osseous and muscular development of the individual; being large, rugged, and massive in most strongly built males; smaller, smoother, and thinner-walled in females and those of slight physique. Its posterior border is only partly marked by the deep digastric fossa or groove, which intervenes between its apex and the skull-base; anteriorly its convex external surface slopes inward to become the back wall of the meatus. Above, it may be said to extend to the curving and often ill-defined temporal

ridge; but is better considered to end at the imaginary horizontal line on the level of the upper wall of the external meatus (Fig. 392). Almost exactly at the juncture of these anterior and superior limits there may almost always be found a depressed groove or pit, below which a ridge or spine projects toward the canal. This *spina suprx meatum*, to which Bezold especially directed attention, is present in the great majority of cases, and forms as fixed and clear a guiding-point as can be taken, not only for

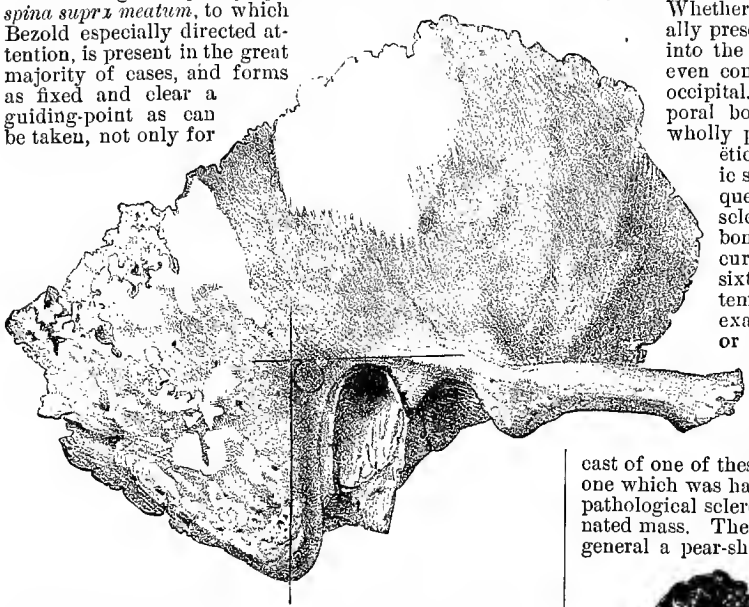

FIG. 392.—Right Temporal Bone, showing the vertical and horizontal lines and the position for opening the mastoid antrum. (After Nuhn.)

all measurements of the temporal bone, but for the entire cranium. It was absent or very ill-defined in but five temporal bones among one hundred and eighty in my collection, examined as to it—every time on the right; Kiesselbach found it in eighty-two per cent. of juvenile and eighty-seven per cent. of adult bones.

The median surface of the cranium, at the part which may be considered the inner surface of the mastoid, is grooved more or less deeply by the sigmoid sulcus to accommodate the lateral sinus, which is formed by separation of the layers of the tentorium in its posterior part, but is wholly in the posterior cranial fossa as it passes down to the jugular foramen. The middle cerebral fossa is partly formed by the squama and reaches downward toward the upper wall of the canal. The height of its floor is subject to great individual differences, and also at different points of the same bone, being lowest in front and rising backward. It is, however, practically never so low as the base line of the mastoid, although not rarely lower than the temporal ridge. It cannot be said, like the lateral sinus, strictly to belong to the anatomy of the mastoid; yet it has too great practical importance to be omitted in our consideration of the field of operation.

FIG. 393.—Metal Cast (freed by corroding away the structure of the bone itself) of the Spaces of an exceedingly Pneumatic Mastoid, showing the large cells so developed that only the thinnest septa remained to separate them. (Randall, Corrosion Anatomy.)

The interior of the mastoid is more or less filled by cavities, usually pneumatic, and lined by extensions of mucous membrane from the tympanum, with which they communicate. They may serve some unknown physiological purpose in connection with hearing, but probably they are only to be regarded as rarefactions of its structure. Hence they are hardly in existence when the mastoid forms but a tiny tubercle in infancy; but they increase in number and size with the growth of the process, and exhibit extreme growth by the thinning of walls and septa and the coalescence of adjacent cells in the rarefied bones of senile individuals. Whether pneumatic or diploëtic, they are generally present throughout the process and extend into the adjacent squama and petrous, and may even communicate with similar cavities in the occipital. Among two hundred and fifty temporal bones, Zuckerkandl found 36.8 per cent. wholly pneumatic, 20.4 per cent. wholly diploëtic, and varying combinations of pneumatic spaces and diploë in 42.8 per cent. The question as to how often an apparently sclerosed condition may be met in normal bones is still an open one, although its occurrence is well established. Among sixty-five pairs and fifty single macerated temporal bones, in the writer's collection, examined in this regard, only twenty-three, or thirteen per cent., showed absence of completely pneumatic structure throughout, although in sixty-two more, or thirty-five per cent., the cortex and the intra-cellular walls were thick and massive. Fig. 393 shows a metal cast of one of these fully pneumatic mastoids, Fig. 394 of one which was half diploëtic, and Fig. 395 one in which pathological sclerosis had rendered it a nearly solid, eburnated mass. The pneumatic cells are claimed to show in general a pear-shape (Figs. 396 and 397) and a radiating

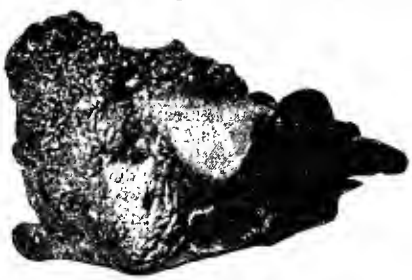

FIG. 394.—Metal Cast of the Spaces of a Temporal Bone, in which only the portion of the mastoid adjacent to the antrum was occupied by pneumatic cells, while the major part of the process was diploëtic. (Randall.)

direction, the smaller ends pointing toward the mastoid antrum, with which they communicate. This antrum, which has been generally described as the most constant in size and position of the mastoid cells, is really the upper posterior cavity of the tympanum, being full-formed at birth and of about the adult dimensions. Its later changes are principally in the fenestration of its walls for communication with the adjacent cells. The antrum is superficial in infancy, its outer wall and part of the

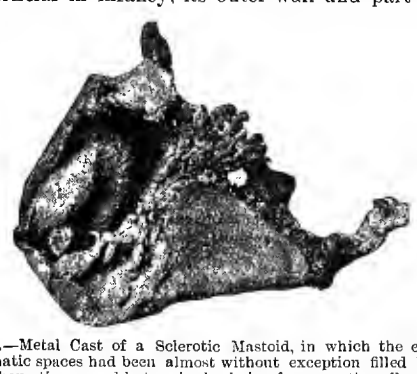

FIG. 395.—Metal Cast of a Sclerotic Mastoid, in which the extensive pneumatic spaces had been almost without exception filled by eburnated bone tissue, and but a single chain of pneumatic cells extended down from the antrum to the tip of the mastoid process. (Randall.)

upper being furnished by the thin vertical plate of the squama; but the thickness of the outer plate increases with maturity, reaching an average of 12 mm. as the squama grows outward to form the bony external meatus (Fig. 396). There is no dividing-line above between the antrum and the attic (*recessus epitympanicus*), the thin *tegmen* roofing in both cavities (Fig. 400, upper half); but the facial and external semicircular canals form a lower median prominence, which serves to narrow the communication and constitute the *aditus ad antrum* (Fig. 400, lower half). Measured from the middle of this threshold the antrum is 10 to 12 mm. in length, while about 6 mm. in breadth and height. Leidy describes backward and outward extensions of the antrum as occurring at times. Its long axis is about the same as that of the tympanum and tube, and at an angle of some fifty degrees to the axis of the external meatus (Fig. 401); but one case was found by Bezold where, on each side, the antrum lay above, and not at all behind the meatus. Its innermost end is, therefore, close above the upper posterior extremity of the auditory canal, but it diverges from it as it passes back and out, and the intervening wall of bone is wedge-shaped, as it increases to 4 or 5 mm. in thickness. This septum is rarely solid, but so occupied by small cells that the actual bony separation is quite readily broken down by antrum disease and a fistulous opening formed into the upper back part of the meatus.

The groove upon the inner posterior surface of the mastoid for the lateral sinus (*sulcus sigmoideus*) is one of the most varying features of the temporal bone. Generally distinct, but shallow, and presenting gentle curves, it may be almost too faint for recognition (Fig. 398); or again of double the usual size and with strongly pronounced curves and margins greatly overhanging (Fig. 399). Receiving the superior petrosal at about the point where it turns downward, and the inferior petrosal near its entrance into the jugular fossa, it experiences some change in size and form on this account. It gives off generally a good-sized emissary vein near the lower turn, which deeply grooves the bone at times in its passage to the mastoid foramen, where it unites with branches of the external jugular system. Rarely this emissary receives nearly or quite all of the blood of the lateral sinus, and may present quite a bulla where it enters the bone; the jugular foramen then giving exit merely to the inferior petrosal. Sac-like bullæ are also found upon the anterior part of the lateral sinus, and may thin the bony wall toward the meatus or the mastoid surface, even forming a considerable dehiscence. The bony surface of the sulcus is generally entire, though often as thin as paper between it and the adjacent cells; yet dehiscence here is only a little less rare than in the tegmen.

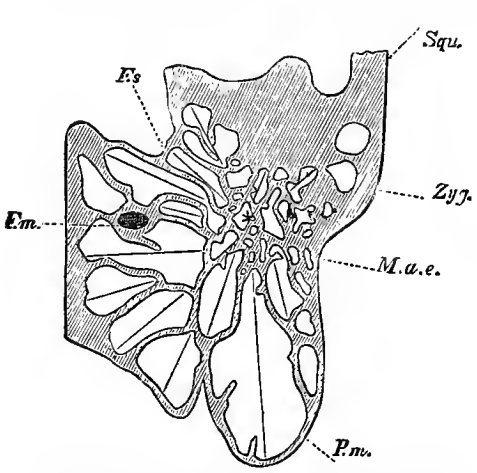

Fig. 396.—Vertical Section of Mastoid Process at Right Angles to the Axis of the Auditory Canal, showing highly developed pneumatic cells and their radiating relation to the antrum. (After Eysell.)

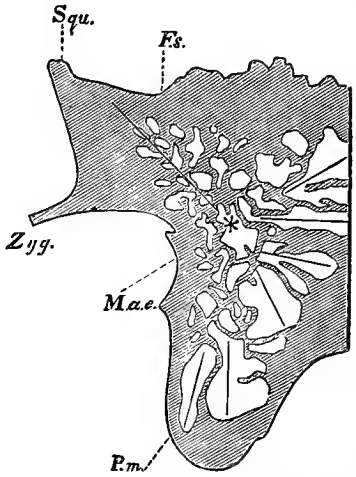

Fig. 397. — More Compact Temporal Bone, cut vertically at right-angles to the auditory canal and showing thicker septa of bone and medium-sized cells. (After Eysell.)

The relation of the sigmoid sulcus to the outer surface of the mastoid and to the back wall of the canal depends upon a series of varying factors. The sinus which it accommodates varies greatly in size, form, and position. The mastoid process presents very differing dimensions, wholly independent of the blood-vessel, and the interposed bone may be solid, diploëtic, or full of pneumatic cells, and thus present wholly dissimilar grades of protection against injury in the opening of the mastoid. Indeterminate as the mastoid process is in size, there is usually fair symmetry, so that the form of one mastoid when concealed by swelling may generally be determined from a study of the other. In a study of forty-eight pairs of bones Bezold found an average length of the process below the spina of 25.17 mm. on the right, 25 mm. on the left (19 to 31 on each side), with a max-

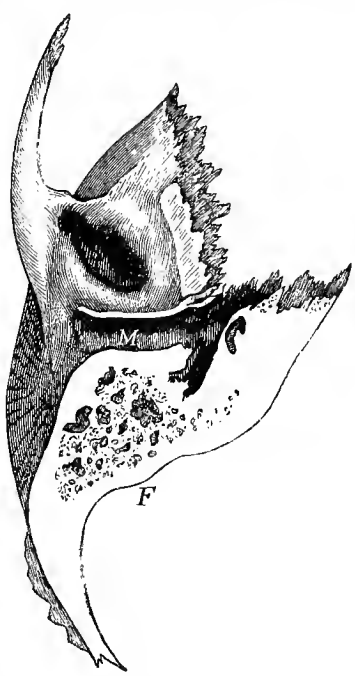

Fig. 398.

Fig. 399.

Figs. 398 and 399.—Horizontal Sections of Right and Left Temporal Bones at the Level of the Middle of the Auditory Meatus, showing the position of the sigmoid sulcus of the lateral sinus at F, in the left far anterior, and closely approaching the meatus and outer mastoid surface; further back, and separated, in the right, by abundant pneumatic cells from the meatus and surface. (After Hartmann.)

imum difference of 5 mm. where the right was larger, and of 3 mm. where the left was larger. Among fifty pairs of temporals in the writer's collection, studied in like manner, the average length was 28.3 mm. (35 to 21) right, 29 mm. (38 to 22) left, with a maximum difference

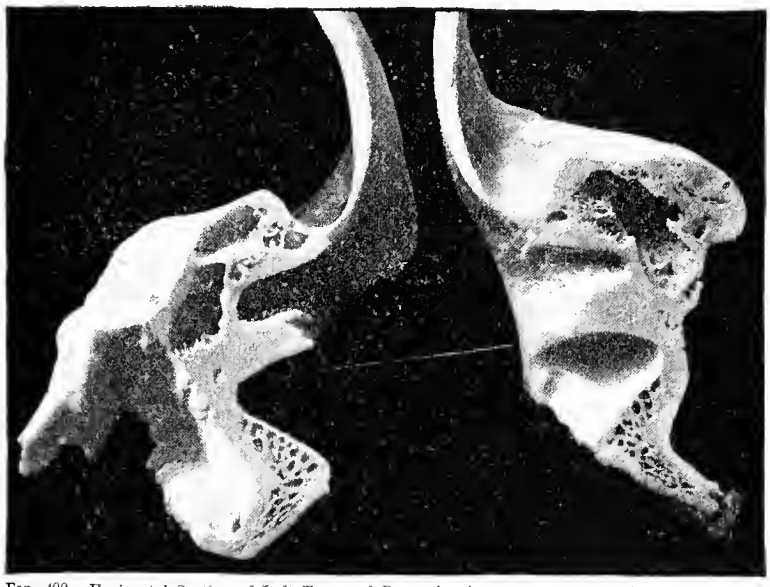

FIG. 400.—Horizontal Section of Left Temporal Bone, showing an extreme anterior and superficial position of the sigmoid sulcus, bringing the lateral sinus almost into contact with the meatus wall and the mastoid surface in the region of the spina, and rendering wholly impossible the ordinary operation for opening the antrum. (Randall, Photographic Illustrations.)

of 5 mm. with larger left, and 3 mm. with larger right. Hartmann measured from the linea temporalis and found an average length of 32.4 mm. (23 to 42) and breadth 26.7 mm. (18 to 35). The less determinate breadth averaged in the writer's series 22.9 mm. (17 to 27) right, 22.5 mm. (16 to 28) left, with a difference only once as much as 3 mm.

No such symmetry exists as to the sigmoid sulcus; on the contrary, one, more often the right, is almost always larger. This larger size of the right sinus, which Bezold, with Rüdinger, estimated at seventy per cent. (although only thirteen right and nine left among his forty-eight pairs), is given as forty per cent. by Schülzke (24 : 5 among 60), was fifty-six per cent. (28 + 5? : 12) among my fifty pairs, and among two hundred and forty skulls was forty-four per cent. (106 + 29? : 59 + 24?). With this larger size, which may be due to the fact that the superior longitudinal sinus generally goes to one side instead of dividing its blood stream at the torcular, and that the right jugular furnishes a shorter and readier path to the heart, there is often a more powerful flow of blood, which may be the reason for a more curved and deeply hollowed sigmoid sulcus. Hartmann and Bezold noted that the sinus extended in about equal proportion outward and forward (Figs. 405 and 406); and Koerner confirmed this so decidedly that he measured only its extension outward to approach the outer surface of the mastoid. Koerner also studied the relation of this curved superficial position to the general form of the cranium (Figs. 402 and 403), and confirmed Bezold's showing that it is more usual in brachycephalics (skulls short for their breadth). These views are combatted by Schülzke, who found little relation between the anterior and the external location of the sinus, and that the more dangerous position was commoner among the dolichocephalic (long and narrow) skulls. This controversy deserves careful statement and analysis, as it furnishes some of our most important data as to the anatomy of the mastoid. Koerner made

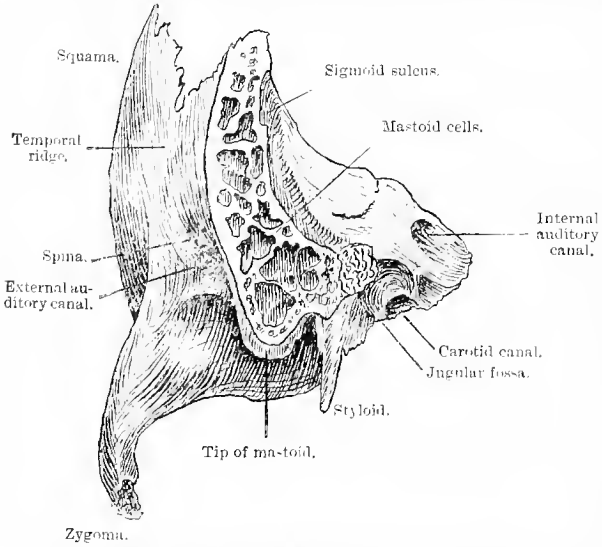

FIG. 401.—Posterior Inferior Aspect of Temporal, sectioned nearly frontally to show the mastoid cells between the lateral sinus and the exterior, generally thin-walled toward the sigmoid sulcus and the digastric fossa within the mastoid tip.

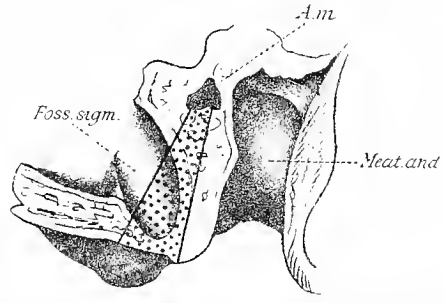

FIG. 402.—Horizontal Section of a Dangerous Temporal Bone, showing the anterior position of the lateral sinus, which closely approaches the auditory meatus and the mastoid surface, and lies in the operation path to the antrum, *A.m.* (After Koerner.)

the claim that the broad skull generally showed a lower cerebral fossa and a more forward and superficial position of the lateral sinus than the skull of lower index; and that this relation was more marked upon the right side. Hence the mere measurement of the length and breadth of a patient's head and consideration of which side is affected would serve to furnish most important prognostic data as to the safety or danger of operation. This relation he ascribed to the incurved line of the mastoid and the upward direction of the pyramid in the

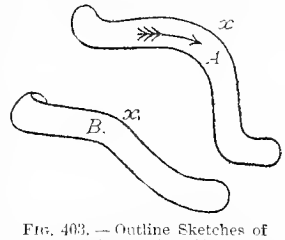

FIG. 403. — Outline Sketches of Casts of the Sigmoid Sulcus seen from the side. *A*, from brachycephalic; *B*, from dolichocephalic skull, showing at *x* the point of greatest curvature and most vulnerable position. (After Koerner.)

brachycephalic skull (as shown in Fig. 405). He measured in sixty skulls the thinnest point of the mastoid over the sinus, and in a later paper gives the data of twenty-seven more, while in a third paper he sets forth the results obtained from horizontal sections of twenty-seven of the same pairs. Yet Koerner's figures show the strange omission of any reference to the position of this most superficial portion of the sulcus, so that it remains wholly uncertain from his data whether the superficial sinus lay in or wholly beyond the field of operation. In Bezold's earlier work this point is well studied, and he gives the average distance of the sinus from the mastoid surface as 7.6 mm. (2 to 17), at an average distance of 15.6 mm. (6 to 24) horizontally back of the *spina supra meatum*. Koerner's results are rather specious, therefore, as to the vulnerability of the sinus. A much more important point was determined by Hartmann among the fifty pairs of bones he operated on and then sectioned. He measured the distance between the lateral sinus and the posterior wall of the auditory canal at about the level of the spina, finding it to vary from 5 to 19 mm. (Figs. 406 and 407), with an average of 11.5. In 41 of the 100 bones it was 10 mm. or less (in 1, 5; in 5, 6; in 6, 7 mm.). In like manner Schülzke found in sixty skulls the meatus-sulcus distance to vary from 3 to 20 mm. It averaged 11.9 mm. (3 to 16) on the right and 13.4 mm. (10 to 19) on the left in nineteen dolichocephalic skulls, and 12.5 mm. (5 to 20) right, 13.7 mm. (5 to 20) left in thirty-six brachycephalic skulls; the general average being 12.4 mm. right, 13.6 mm. left. The maximum difference in any skull was 7 mm. where the right, and 4 mm. where the left, was farther forward. Similar figures from twenty-seven skulls measured by Koerner gave averages of 12.50 mm. for dolichocephalic, 12.28 mm. for brachycephalic, 11.86 mm. right and 12.91 mm. left, with a maximum difference of 7.2 mm. in any one

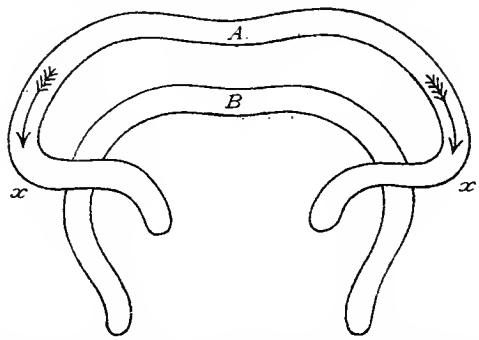

FIG. 404.—Outline Sketches of Casts of the Sigmoid Sulcus seen from above, showing the stronger curves and more outward extension in the brachycephalic, *A*, than in the dolichocephalic, *B*. (After Koerner.)

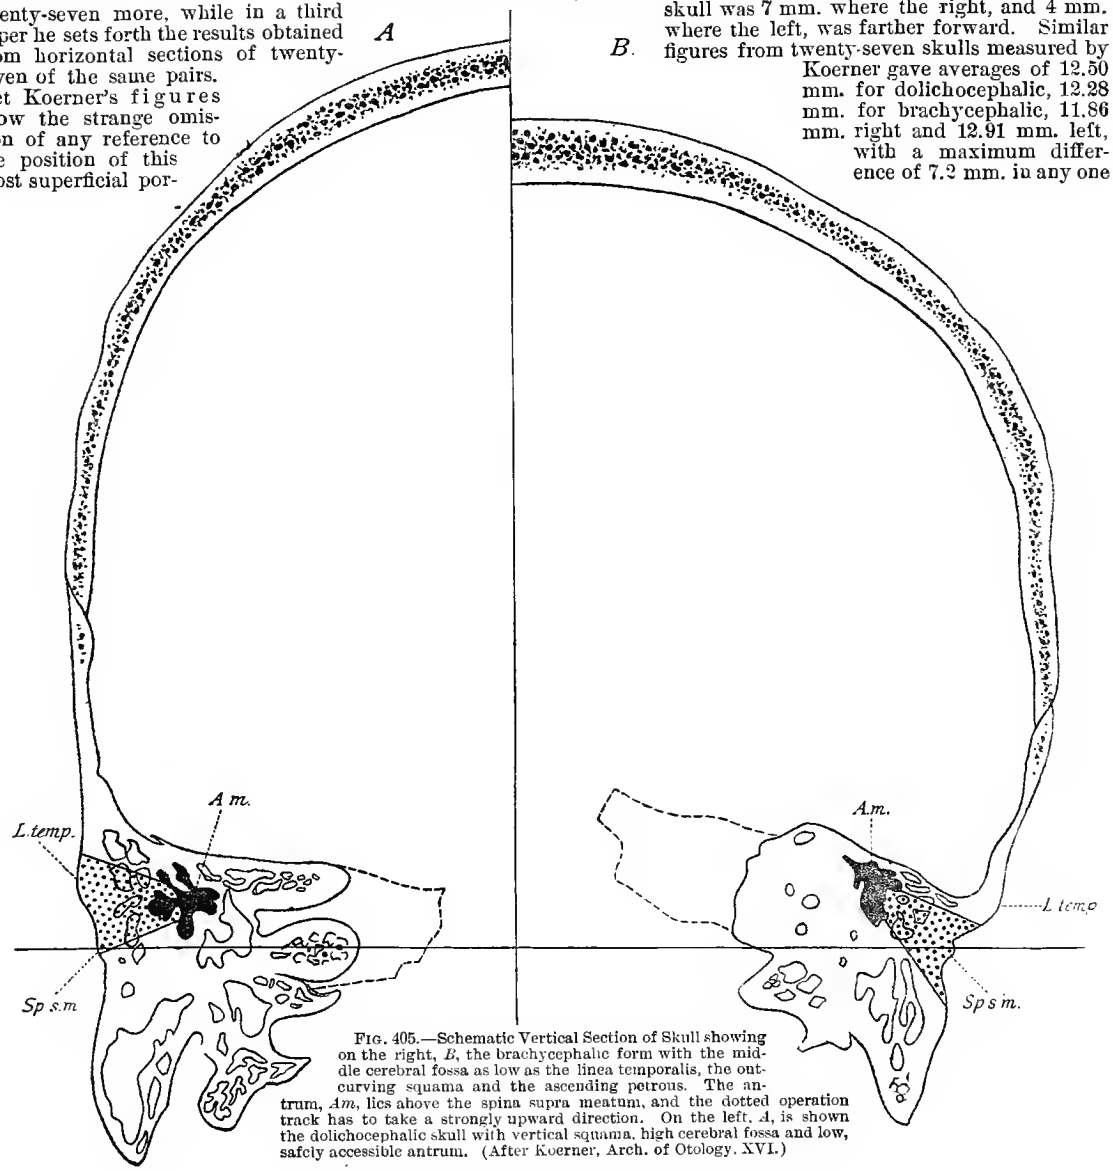

FIG. 405.—Schematic Vertical Section of Skull showing on the right, *B*, the brachycephalic form with the middle cerebral fossa as low as the linea temporalis, the outcurving squama and the ascending petrous. The antrum, *Am*, lies above the spina supra meatum, and the dotted operation track has to take a strongly upward direction. On the left, *A*, is shown the dolichocephalic skull with vertical squama, high cerebral fossa and low, safely accessible antrum. (After Koerner, Arch. of Otology, XVI.)

case. Study of two hundred and forty skulls has furnished the writer with an average of 11.9 mm. (1 to 20) right, 12.8 mm. (0.2 to 20) left, with the right sinus more anterior (13 mm. max.) in 101 and the left (7 mm. max.) in 78. The eighty-five long skulls gave

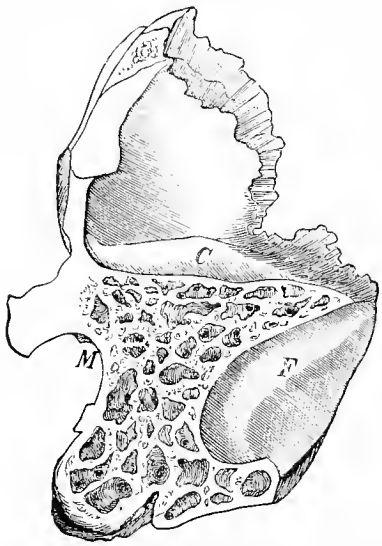

FIG. 406.—Vertical Section of Pneumatic Left temporal Bone at right angles to the Auditory Canal, showing abundant cellular interspace between the sigmoid sulcus and the meatus. (After Hartmann.) (Same lettering as in Fig. 407.)

exactly the same figures as the whole series, while the one hundred and twenty short skulls gave averages of 11.4 mm. (1 to 19 right), 12.5 mm. (1 to 20) left, with the more anterior sinus forty times on the right and forty-four times on the left.

Such figures wholly fail to support Koerner's view,

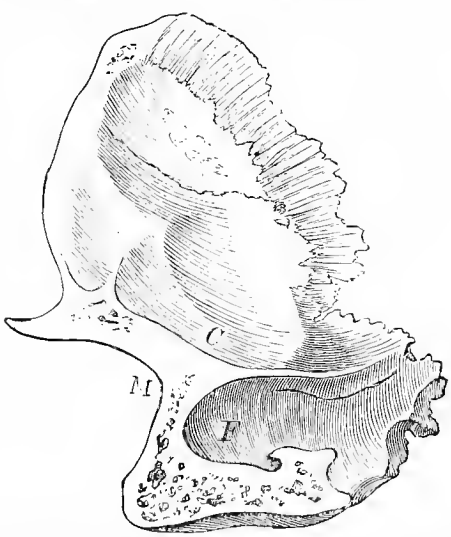

FIG. 407.—Vertical Section at Right Angles to the Canal, *M*, of a diploëtic right temporal bone, showing a forward and superficial position of the sigmoid fossa, *F*, and a low middle cerebral fossa, *C*. (After Hartmann.)

and the choice of the twenty extreme examples at each end of the scale gave averages of 11.5 mm. right (0 to 17) and 13.1 mm. left (9 to 16) for dolichocephalic, as compared to 12.8 mm. (7 to 17) right and 13 mm. (10 to 16) left for brachycephalic. His findings must, therefore, be regarded as accidental. The thinnest point over the sinus, as to which Koerner makes his showing, averaged 7 mm. (0 to 17) right, and 7.5 mm. (0.5 to 22) left, among the writer's two hundred and forty skulls, and its position back of the spina 16.5 mm. (1 to 25) right, 15.8 mm. (1 to 24) left—figures of small significance except in showing, as do the other parts of the study, that minimum results may be met on either side and in any form of skull.

Another series of measurements made by the writer have probably more importance than either of the former. The distance was determined between the most vulnerable point of the sinus and a point 5 mm. behind the spina —thus giving the "operation room" presented by each specimen. This averaged 10.9 mm. (2 to 19) right and 11.7 mm. (1 to 20) left, among 85 dolichocephalic skulls; the right sinus being in the more dangerous position in 43 and the left in 24. For the 120 brachycephalic skulls the averages were 11.6 mm. (3 to 18) right, 12 mm. (1 to 20) left, the more exposed sinus being fifty-two times the right and thirty-eight times the left. For the entire 240 skulls it averaged 11.4 mm. (2 to 19) right, 11.9 mm. (1 to 20) left, with the right the more dangerous in 112, the left in 72, and equality in 56.* In like manner, among the writer's fifty pairs of temporals, the right averaged 9.76 mm. (3 to 16), the left 9.66 mm. (0.5 to 16), the more dangerous side being twenty-one times the right and eighteen times the left. In eight instances the operation room was 5 mm. or less—4 on each side; the maximum difference was 8 mm. with the right, 5 with the left, the greater distance. It appears, therefore, from an analysis of all available data that the right sinus is usually larger, more anterior, and more vulnerable than the left, but in a degree too slight to be of practical moment; while the position of extreme danger may be met on either side and in any form of skull. Bezold's observation that an unsymmetrical skull has the more dangerous sinus on the larger side is as good a guiding indication as we can find.

FIG. 408.—Dehiscent Areas in the Roof of the Tympanic Attic and Antrum of a Right Temporal Bone, with a low middle cerebral fossa. The internal auditory meatus is seen to the left, part of the sigmoid sulcus to the right.

The other limitation of the operative field in opening the mastoid is the position of the floor of the middle cerebral fossa. This cavity extends in rare instances down to the field of the operation, and uncovering or wounding of the dura mater is readily possible in an ill-placed opening (Fig. 407). So long as the *linea temporalis* was accepted as an index of the height of the fossa, blunders were easy, since its variable position furnished no true criterion. The upper wall of the auditory meatus or its adjacent *spina* are now the usual guiding points, and by keeping below these safety is assured. In this matter of the height of the fossa Koerner has thought that a relation to the skull-form can be found, and that the brachycephalic skull and the right side (Fig. 409) are the more dangerous (Fig. 410), and that dehiscence of the tegmen tympani is therefore more common on the right (Fig. 407) and in brachycephalics, with consequent more frequent right-sided cranial involvements. His measurements of 87 skulls showed the height of the fossa above the upper meatus wall to average 11.5 mm. (7 to 17) among the very long, 8.7 mm. (4 to 14) among the less dolichocephalic

* Measurement of these dimensions with one branch of the calipers passed through the foramen magnum in the intact skull probably slightly exaggerates, since an error, fairly uniform throughout the series, and less than a millimetre in amount, was probably introduced from slight obliquity of the placing of the instrument.

skulls, as against 5.2 mm. (2 to 9) in the brachycephalic. Schülzke, on the other hand, found a low fossa (10 mm. or less) in fourteen long, ten medium, and fourteen short specimens, although 36 of his 60 skulls were brachycephalic; and 20 times it was on the left side, and 18 on the right. The average was 11.2 mm. (8 to 17) right,

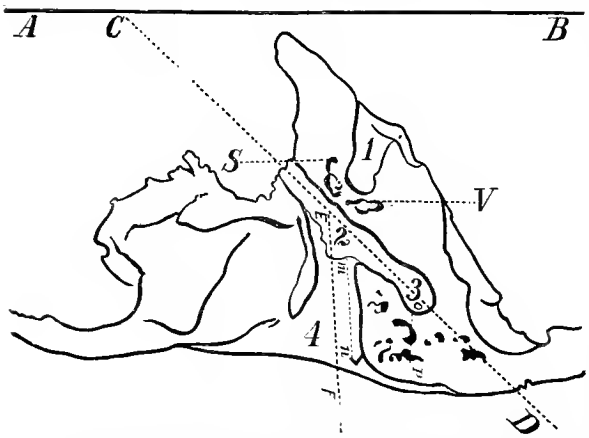

FIG. 409.—Diagram of Right Temporal Bone Sectioned Horizontally and Showing the Inclination of the Tubo-tympanic Axis, *C*, *D*, to the sagittal plane of *B*; the length, *m n*, of the upper back wall of the meatus, and the depth, *o*, *p*, of the antrum from the operation point. (After Allen.)

and 11.1 mm. (8 to 16) left, among the long; 12.5 mm. (8 to 19) right, and 12.2 mm. (8 to 18) left, among the short; with general averages 12.1 mm. right and 11.9 mm. left. The height was equal in 12, differed but 1 mm. in 41, and its maximum difference reached 4 mm. in only one case. In the writer's fifty pairs of temporals the right averaged 4.82 mm. (1 to 10), the left 5.41 mm. (2 to 11), with a maximum difference of 4 mm. among the 23 where the right fossa, and 12 where the left, was lower. In his study of this point in 240 skulls, the writer determined the vertical height of the fossa above the spina and the lateral displacement in the frontal plane within or beyond the spina. The averages were 6.5 mm. (1 to 14) right, and 6 mm. (0 to 14) left, with the left fossa lower in 138 and the right in 53. It was a shade lower in the brachycephalic—6 mm. (1 to 14) right and 5.8 mm. (0 to 14) left—than in the dolichocephalic—6.6 mm. (1 to 14) right and 6 mm. (1 to 12) left. The lowest point thus determined generally lay within the spina, sometimes 5 mm. internal, at times 5 mm. external, to it; while in some cases where it was but 1 mm. above, it was exactly over the spina. In no instance was it below the spina; although at times lower than the upper margin of the auditory meatus. In these measurements the extreme length and breadth of the skulls were taken to obtain the index, as was done was by Schülzke, in accord with most craniologists; although Koerner had used the breadth between the parietal protuberances. The distance was also measured from spina to spina, and from sulcus to sulcus within, at the widest point. It was thus shown that the sinus, like the middle cranial fossa, not rarely lay farther outward than the spina or the more prominent operation point, yet was far enough back to be well out of reach and covered by 5 to 7 mm. of bone. It was therefore evident that the form and convexity of the mastoid process itself play an important part; and that irrespective of the size and position of the sigmoid sulcus there may interpose a thick wall of compact or cellular bone to protect the sinus, even when its large size and sweeping curves make the danger of its position seem inevitable. This question, therefore, of the exterior configuration of the mastoid process, as revealed to palpation of one or both bones, may be really our very best indication as to the probable safety or danger of operation on the bone before us, as was pointed out by Bezold. A large mastoid, with not too deep a concavity below the temporal ridge and its convexity in the horizontal plane passing gently into the auditory canal, is probably safe; but there is no possibility of predicting the real condition, and nothing can relieve the surgeon of the duty of operating as though the case were known to be very dangerous.

The cells of the pneumatic mastoid are generally largest and thinnest-walled at its apex and especially upon its median aspect toward the digastric groove. Hence suppuration may rather readily break through in this region, especially when the outer mastoid cortex is thick. Dehiscence is not rare in this region, and may be met upon the outer aspect; but emphysema from such a condition almost never occurs.

The third structure to be avoided in opening the mastoid is the prominent inner wall of the antrum, where lie the facial and the horizontal semicircular canals. Generally these lie deeper than the part of the antrum reached by the operator; yet in a sclerotic mastoid there may be danger of striking them when the antrum is not found. These structures are never farther outward than the upper posterior tympanic margin, and this point may usually be found with the probe on the patient and its depth used as a guide. It is easily measured on the macerated bone, and its distance from the spina is given as 12 to 17 mm. by Allen. In my fifty pairs of temporals it averages 17 mm. (14 to 20) from the spina, and 19 mm. (16 to 21) from the operation point, 5 mm. back of the spina. A penetration of 15 mm., therefore, could hardly in any case wound these structures. Yet in many cases uncovering or necrosis of the bone may render uncertain the limits of the antrum, while calling for curretting of the surface. Cautious efforts should, therefore, be made to determine the location of these very important canals, since penetration of the semicircular canal may be the death-blow to the auditory apparatus, and through it or the facial, pus may readily penetrate to the cerebral base with fatal effect.

A point formerly more considered, and still practically

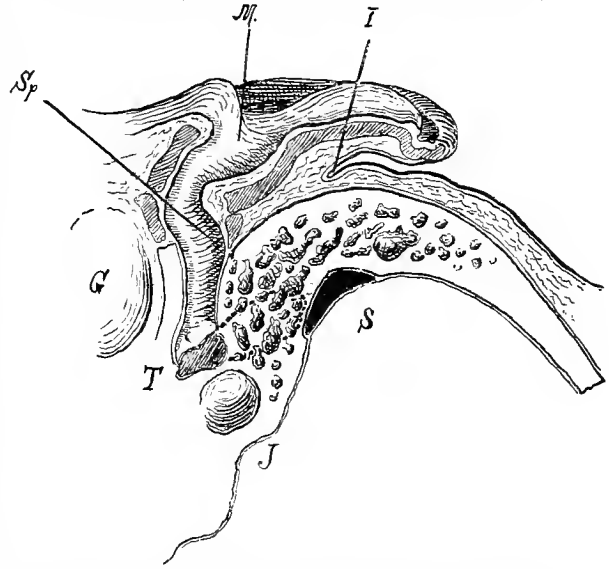

FIG. 410.—Horizontal Section (upper half) of the Left Ear, with the Soft Parts in Place, showing the location back of the meatus, *M*, and the spina, *Sp*, of the posterior insertion of the auricle, *I*. The glenoid cavity, *G*, the tympanum, *T*, and the jugular, *J*, are also shown; and the sigmoid sinus, *S*, which in this case is safely distant from the field of operation, is seen to be most superficial opposite the insertion of the auricle.

well worthy of mention, is the relation of the soft parts to the more important bony structures beneath. The incision preliminary to opening the mastoid has generally been made 5 to 10 mm. back of the insertion line of the auricle and not carried down very far toward the mastoid tip in order to avoid the branches of the posterior auric-

ular. Only to the aural specialist long unaccustomed to general surgery has the spirting of these little arteries any importance. Even in the swollen and infiltrated tissues they can generally be readily seized with hæmostats and afterward twisted, should they tend to bleed at all when released. It is more important, perhaps, to cut slightly behind the insertion of the auricle, in order that there may be the least projection of the pinna subsequently. The old rule that this insertion marked the point for entering the bone, has been wholly superseded; and it may be better said to mark the usual location of the most superficial part of the sinus (Fig. 411). According to Bezold it averages 15 mm. behind the spina, but Hartmann's finding of 10 to 12 mm. is probably more accurate. The older operators usually selected the area thus posterior to the auricle for entrance; modern operators usually work in the area covered by its insertion. A third location has been advocated as the best site for all cases—as it certainly is for some—the mastoid surface anterior to the spina, which constitutes the posterior wall of the auditory canal. For a case like that shown in Fig. 410, no other entrance would be possible at the usual level. Here we may be sure of thin bony plates to be opened, and a shorter, safer path to the antrum. Yet a little swelling of the soft tissues of the canal will serve to impede greatly free access to such an opening or the free exit of discharge; and whether made from the canal or from the incision back of the auricle, it is probably rarely so satisfactory as the more usual perforation.

The thin walls of the cells upon the median surface of the mastoid tip have been referred to. They are sometimes dehiscent, as Bezold found four times among 200 skulls, and often so thin as to be broken in the specimens; in 22 they could be readily pierced with a needle. Hence it is easy for pus to break through into the digastric fossa, thence to burrow beneath the fascia of the neck to form post-pharyngeal, deep cervical, or even mediastinal abscesses. Generally in the cases of this sort clinically met, there is a distinctly excessive thickness (whether natural or pathological, of the outer lamella of the mastoid, which probably as greatly influences the result as does the thinness in the digastric fossa. Such pus collections are apt to be concealed from ready detection by the interposition of the bony process and the tendon and muscle of the sterno-mastoid, which may, as a whole, be pressed outward. Surgical common-sense seems to demand that these cases should be attacked at the posterior margin of the digastric groove, where the neck abscess and the mastoid empyema are both within reach, the pus fully evacuated, and then such counter-openings made as the case may demand. A sinus can generally be found upon the digastric surface of the bone, and through it the interior can be emptied of pus and granulations, so that irrigation can pass freely in to the tympanum; yet a more typical opening of the outer surface of the bone at or below the usual point is also called for to give free access to the antrum. Bezold, indeed, now does this alone, neglecting the lower opening unless compelled to interfere here also; yet this seems to ill accord with the anatomical conditions presented.

The anatomy of the juvenile mastoid presents great variations according to the age, as has been previously suggested. A mere tubercle upon the surface of the infant temporal, some distance from the lowest part of the bone, the mastoid process changes in every respect as it grows. Small as are the general dimensions of the bone, some parts are full-sized even thus early. The tympanum undergoes little change in after-years, except in being separated from its fellow by the growth of the skull base between, and more deeply buried by the outward growth of the auditory canal. The size of the antrum, as of the other portions of the tympanum, increases little after birth; but while the bony wall separating it from the exterior grows from almost nothing to a thickness of 10 to 15 mm., the separation from the lateral sinus steadily decreases (Fig. 411). Hartmann found this wall never less than 3 mm., generally 4 mm., in 21 temporals of new-born infants; while in 12 bones of children from one to five years it averaged 2 mm., but was hardly 1 mm. in 5. This is due to the pressing forward of the lateral sinus as it grows, grooving more deeply the inner aspect of the petro-mastoid. It thus tends to approach the auditory meatus, for while in 40 infant bones measured by Hartmann the meatus-sulcus

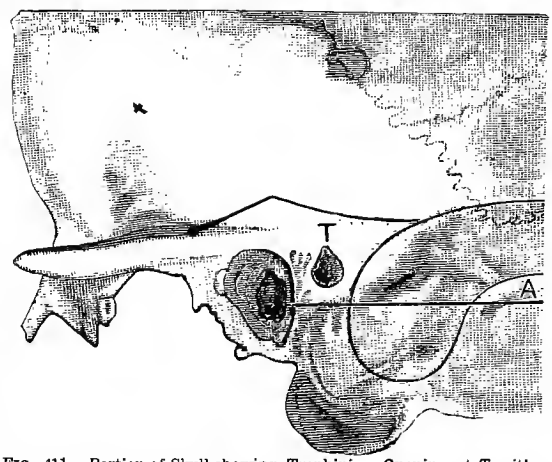

FIG. 411.—Portion of Skull showing Trephining Opening at *T*, with a dark line above to indicate the usual height of the middle cerebral fossa, the curved lines posteriorly to show the usual limits of the lateral sinus and the horizontal line at *A*, part of Reid's base line, passing through the lower edge of the orbit and the occipital protuberance. (After Birmingham.)

distance averaged 12 mm., and was never less than 10 mm. in the 12 bones of children from one to five years, it was sometimes but 8 mm., with an average of 10 mm. In 16 bones of individuals from five to twenty years it averaged still less. Similarly the writer found among 10 temporals of new-born infants in his collection a distance averaging 6 mm. (4 to 7 mm.) between the sulcus and the antrum, and 13 mm. (11 to 14 mm.) between the sig-

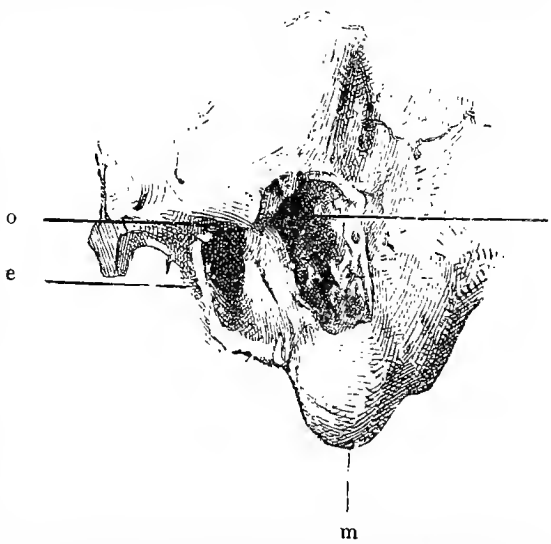

FIG. 412.—Left Temporal Bone Chiselled to Open the Mastoid Cells and Antrum. The opening, although not so extensive as sometimes figured and advocated, could be safely thus made in only a fraction of cases. (After Politzer.)

moid sulcus and the meatus. This latter dimension had an average of 11 mm. (8 to 14 mm.) among 15 temporals of children from one to five years of age, the smaller distance being in the more developed bones—figures a little greater than the average in the adult, and presenting no such minimal measurements as are there often found. The antrum is, therefore, readily reached at little depth

in the child, and the lateral sinus is generally well back of probable injury. The middle cerebral fossa is generally low (1 to 5 mm.), averaging 3 mm.; and in not a few instances a large venous sinus deeply grooves the most vulnerable outer portion of it. The spina is more often lacking and the outer margin of the meatus is less well-defined than in the adult; so special care should be taken to avoid penetration at too high a point.

MATLOCK. A favorably known spa and summer resort in Derbyshire, England.

LOCATION.—Matlock is situated on the banks of the river Derwent, between the sheltering tors of Matlock Dale. The place is noted for its agreeable summer climate just as much as for its indifferent thermal springs. Bradshaw describes the place as follows:

"Matlock Bath is built partly in a valley, through which flows the river Derwent, and partly upon terraces of tufa, deposited from its warm springs. It is sheltered from the north and east by the heights of Masson and the High Tor. To the south and across the Derwent are the grounds of Willersley Castle. There is a large pavilion in which a band plays and concerts are given during the summer, and a promenade by the side of the Derwent. The neighborhood is very beautiful and picturesque."

ACCESS.—Matlock Bath is reached by the Midland Railway in a four hours' trip from London.

ANALYSIS.—The temperature of the springs is 68° F. Their chief mineral ingredients are magnesium sulphate, carbonate of lime, and sodium chloride. But the solids amount to only about thirty grains per gallon of the water. Matlock water is palatable, owing to a fair proportion of free carbonic acid gas.

INDICATIONS.—Matlock is resorted to in cases of gout, rheumatism, bladder affections, skin diseases, and mild neuroses. Scrofula is also said to be treated with good results there.

ACCOMMODATION.—The bathing establishments, hotels, and lodging-houses are only moderately comfortable.

Edmund C. Wendt.

MENINGES (THE ENVELOPES OR MEMBRANES OF THE BRAIN AND SPINAL CORD). § 1. *Introductory Note.*—During the preparation of the present article points supposed to be clear have proved to need further elucidation, and problems altogether unexpected have arisen, demanding for their solution time, material, and apparatus at present unattainable.* Indeed, so impressed has the writer become with the vagueness, inadequacy, and inconsistency of current accounts, and with the necessity for a re-examination of the meninges in all their relations, that only a sense of obligation to the patient and considerate editor who has entrusted him with the subject stands in the way of retreat at the eleventh hour. Necessarily transmitted to the printers at a certain time, the article is neither so clear, consistent, correct, concise, nor complete as the writer would wish it to be. The least unsatisfactory position relates to the question of the existence of a natural communication between the true cavities of the brain and the spaces ectad of it.

Of the eleven figures four (418, 420, 421, 422) are original. One (423) is from Henle, and one (417) from Sappey. The diagram, Fig. 416, from Dr. Langdon's paper, 1891, is kindly loaned by the author. The remaining four (413, 414, 415, 419) are copies of the reductions of figures by Key and Retzius in Quain's "Anatomy."*

In quoting from these and other works the terms preferred by the present writer are commonly employed. See the article, "Anatomical Terminology," in Vol. VIII.

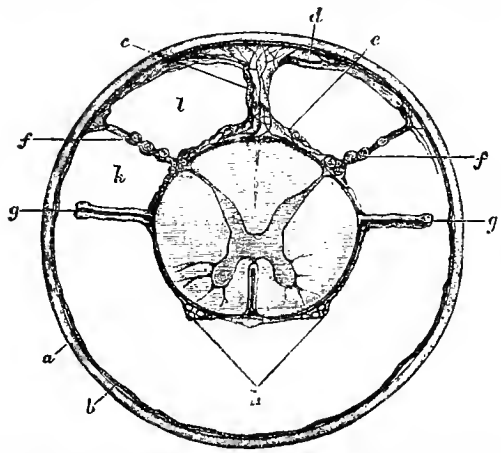

FIG. 413.—Transection of the Myel and its Meninges in the "Upper" Thoracic Region. Enlarged somewhat from Key and Retzios (Taf. i., Fig. 7), after Quain (iii., Fig. 132). *a*, Dura (not the spinal periosteum, but representing the ectal layer of cranial dura); *b*, arachnoid; *c*, septum posticum; *d*, *e*, *f*, trabeculæ in the subarachnoid space, those at *f* supporting the dorsal (posterior) nerve-roots; *g*, ligamentum denticulatum; *h*, ventral (anterior) nerve-roots, cut off; *k*, *l*, subarachnoid spaces. The pia is not designated, but may be recognized as the double outline of the myel dipping into the dorsal fissure as a narrow septum and into the ventral as a fold.

Note.—The foregoing is substantially the description in Quain. But some of the writer's observations lead him to suggest that the spinal, like the cranial, arachnoid comprises two layers, a dural and a pial, connected by the reflected layers of the septum posticum. This view, however, would homologize the space *k*, *l*, with the intrarachnoid space of the cranium, and hence their free communication with the postcisterna would be difficult to explain.

§ 2. Points illustrated by Fig. 413.† A. The subcylindrical form of the myel, and the relations of the areas of alba and cinerea at this level; for these and most of the other features shown in this figure see the account by Spitzka, Vol. VIII., pp. 476–477.

B. The existence of a dural sheath (theca) of the myel, independent of the periosteum, the two being united in the cranium.

C. The somewhat loose adhesion of the arachnoid to the dura, leaving slight and scattered subdural spaces.

D. The presence of the *septum posticum* at this level; it is said (Quain, iii., 188) to be most perfect in the cervical region, and more or less incomplete farther caudad.‡

E. The size of the subarachnoid space traversed by the

* The conditions of investigation of the meninges are peculiar. The pia and arachnoid are relatively delicate: they are easily torn and their attachments ruptured. But they are surrounded by an unusually tough membrane, the dura, and the whole is enclosed within a case of bone which must be sawn or otherwise forcibly opened by measures which are almost sure to rupture the pia and arachnoid. It is much to be desired that the whole subject be reviewed by some anatomist having the use of a mechanical bone-cutting apparatus, *e.g.*, the electro-osteotome of Dr. M. J. Roberts.

* Besides those here included, the new figure, 182, of the tenth edition, vol. ii., is worth consulting, although not altogether satisfactory.

† See note under the description of Fig. 413.

‡ *Septum posticum* is an undesirable term, but *septum dorsale* might be confounded with the prolongation of the pia into the dorsal fissure of the myel.

spinal nerve-roots, the trabeculæ, and the *ligamentum denticulatum*.

F. The location of the *ligamentum denticulatum* at either side of the myel. As shown in Vol. VIII., Fig. 5047, 9, 9, 9, and described on p. 477, this is a fibrous band connected with the pia, and reaching the dura by a triangular extension in the intervals between the nerve-

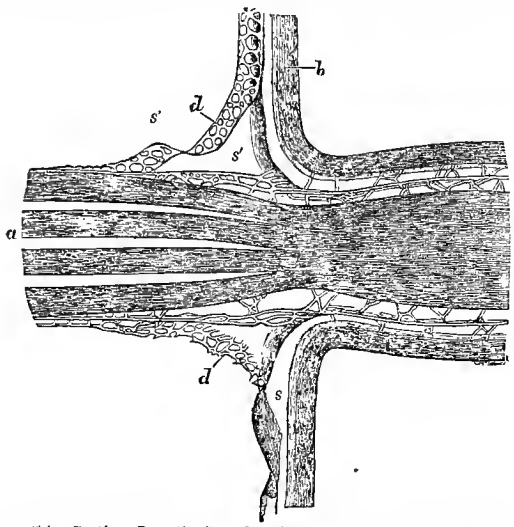

FIG. 414.—Section, Lengthwise, of a Ventral Nerve-root at its Place of Exit from the Spinal Canal. Enlarged. From Key and Retzius (Taf. i., Fig. 10) after Quain (iii., Fig. 128). *a*, Four funiculi uniting to constitute the root; *b*, dura reflected upon the root at its emergence through the intervertebral foramen (the periosteum is not shown); *c*, arachnoid; *d*, reticular lamella of the arachnoid reflected upon the root (compare Fig. 413, *f*); *s*, subdural space; *s'*, subarachnoid space.

roots; but opposite the roots (as in this figure) it is narrower, and does not reach the dura.

§ 3. *Definitions.—Meninges* is the plural of *meninx*, from the Greek μῆνιγξ, signifying any membrane or coating, as of the eyeball, and even the scum upon milk or wine; but, as stated by Hyrtl ("Onomatologia," p. 324), the word was restricted by Aristotle ("Hist. Anim.," lib. i., cap. 16) to the coverings of the brain (and myel ?), and the limitation has been since maintained. The synonyms of *meninx* are: Fr., *méninge;* It. and Sp., *meninge;* Ger., *Hirnhaut.*

§ 4. *The Three Meninges.*—Nearly all anatomists recognize three chief membranous envelopes between the substance of the neuraxis (brain and spinal cord) and the cranio-spinal canal, viz.: An ental, the *pia;* an ectal, the *dura;* an intermediate, the *arachnoid.* Their relative positions when the cranium is opened are indicated in Vol. VIII., Fig. 4687. Properly speaking the pia pertains to the neuraxis, and the dura to the cranio-spinal canal, while the arachnoid has more or less varied relations to both the other meninges. All three present differences according to their location within the cranium or the spine, and there are transition conditions in the cephalic portion of the latter which are not yet fully made out.

The term *pachymeninx* (tough envelope) is sometimes used for the dura, irrespective of the recognition of a parietal layer of arachnoid. In like manner *leptomeninx* (tender envelope) is sometimes used for the pia and the commonly admitted visceral layer of arachnoid. The pathological terms, *pachymeningitis* and *leptomeningitis*, are derived from these words.

§ 5. Points illustrated by Fig. 414. A. The formation of a nerve-root from the union of several funiculi or rootlets.

B. The extension of the myelic dura upon the root at its exit from the spinal canal, to be lost in the sheath of the nerve.

§ 6. *The Pia.*—This was formerly more often called *pia mater,** sometimes also *meninx vasculosa* (Ger., *dünne Hirnhaut, weiche Hirnhaut;* Fr., *pie-mère*). It is delicate, fibrous, highly vascular, and intimately connected with the neuraxis, into the substance of which it sends numerous nutrient small vessels. When stripped off, these vessels commonly break at a short distance from the pia, and their number and minuteness impart to the ental surface of the membrane a flocculent or woolly aspect, the *tomentum;* Vol. VIII., p. 111, § 11, F.

§ 7. *Myelic Pia.*†—This is thicker and firmer than the encephalic, less vascular, and more closely adherent to the nervous substance. It has sometimes been called the "neurilemma of the cord." Two layers are recognized: the ental, sometimes called *intima pia*, sends a fold into the ventral ("anterior") fissure, and into the dorsal a lamina not recognizable as a fold. Along the ventrimeson the pia presents a conspicuous fibrous band, the *linea splendens*, not represented in Fig. 413.

§ 8. *Points Illustrated by Fig.* 415.—A. The relative positions of the meninges; compare Fig. 416 and Vol. VIII., Fig. 4687.

B. The formation of the longitudinal sinus within the substance of the dura.

* The reduction of the polyonyms, *pia mater* and *dura mater*, to the mononyms, pia and dura, was urged by the writer in 1880 in a paper before the American Association for the Advancement of Science. Since that time the use of pia and dura, and of the natural adjectives, pial and dural, has become quite general. The simplification has been recommended by the Association of American Anatomists (December 27, 1889) and by the American Association for the Advancement of Science, 1890 and 1892.

† The paragraph in Quain (iii., p. 186), which is here substantially reproduced, is sandwiched, as it were, between two captions that might obscure it.

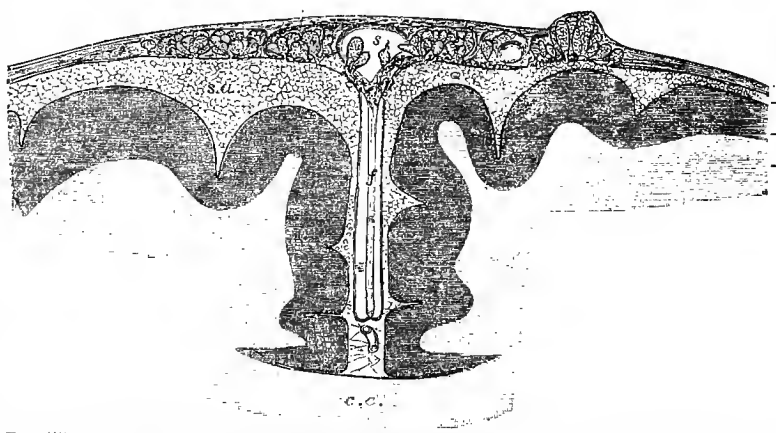

FIG. 415.—Transection of the Dorsal, Mesal Region of the Cerebrum, to show the Meninges and Arachnoidal Villi. Slightly enlarged. From Key and Retzius (Taf. xxix., Fig. 4) after Quain (iii., Fig. 134).

Preparation.—The spinal subarachnoid space (Fig. 413, *k*, *l*) was injected with a fine blue mass, which filled (and distended ?) the corresponding space upon the cerebrum and entered the arachnoid villi. The original figure is appropriately colored and on a larger scale. Judging from the relation between the width of the falx, and the interval between it and the callosum, the plane of section was not far cephalad of the splenium; see Fig. 418. *c.c.*, callosum; *f*, falx; *s*, falcial sinus; *s.a.* (at the left), subarachnoid space.

Defects.—The pia is not as distinct as the writer would make it. The relation of the arachnoid to the ventral margin of the falx is not quite clear. There is no extension of the cortical cinerea upon the dorsum of the callosum as an indusium; see p. 104, § 47. There is no indication of the existence of the two layers of the dura, *e.g.*, periosteal and encephalic, described by Spitzka (Vol. VIII., 47) and Langdon (Fig. 416). The falcial (inferior longitudinal) sinus may have been absent in this case, as it is said to be in many (Browning, Vol. VIII., 241). The *lacunæ laterales* are somewhat indistinct, probably in consequence of the reduction from the original figure, where they are much more clearly shown.

C. The projection of the arachnoid villi into the sinus and the parasinual spaces; see Browning, Vol. VIII., p. 242.

D. The accumulation of the villi at one point, on the right, to such an extent as to cause the protrusion of the dura, and presumably a depression of the ental surface of the cranium.

E. The separability of the arachnoid from the pia, leaving a distinct subarachnoid space increased along the fissure lines.

F. The conterminousness of the arachnoid and the falx, and their separation by a distinct interval.

§ 9. *The Encephalic Pia.*—According to Quain (iii., 186), only the ental of the two myelic layers of the pia is represented on the brain, but where and how the other layer disappears is not stated. The pia follows all the undulations of the encephalic surfaces, dipping into the fissures and rimulas as folds or rugas of corresponding depth; see Fig. 300 and Vol. VIII., Fig. 4687. At the bottom of the intercerebral fissure, the mesal cleft between the dorsal portions of the two hemicerebrums, the pia enters the callosal fissure at either side, is then reflected, and crosses the callosum.

Since the pia is practically the ectal surface of the brain, its cut edge is not commonly represented excepting when the figure is on a very large scale; but on diagrams its vascular character may be instructively indicated by a red line.† Sometimes, as in Fig. 59, § 43, 6, the pia forms the only boundary of an area.

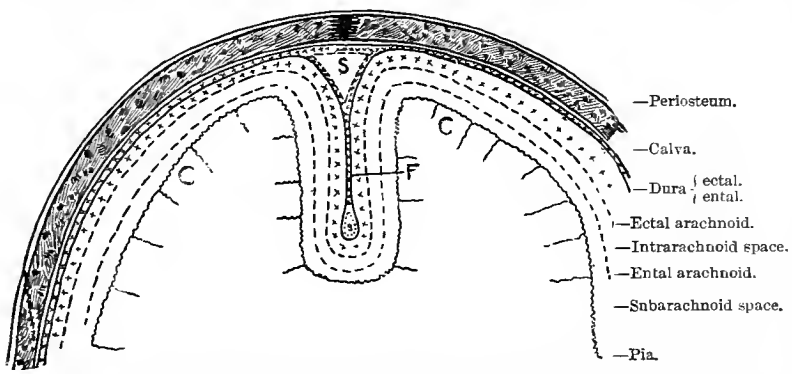

FIG. 416.—Schematic Transection of the Parietal Region of the Newborn, to show the Relations of the Meninges to the Cerebrum and Cranium. From F. W. Langdon, 1891. C. C. cerebrum; F, falx; S, longitudinal sinus; xxx, subserous connective tissue between the dura and the ectal arachnoid.

*Defects.**—The mesal dark area dorsad of S (the longitudinal sinus) represents the ligamentous connection of the two parietal bones; it should be continuous with the periosteum and ectal dura. The "subserous dura," between the dura and the arachnoid, represented by the series of crosses, is made too wide in proportion.

§ 10. *The Telas.*—As has been described in Vol. VIII., p. 118, § 44, Fig. 4707, the cœlian parietes, *i.e.*, walls of the true encephalic cavities, typically comprise three concentric layers, viz., an ental endyma, an ectal pia, and an intervening brain-substance. The endyma and the pia are nearly uniform in thickness and constitution: the nervous layer varies considerably in cellular structure and even more in thickness, from thin and apparently functionless areas, terma, valvula, etc., to the enormously thickened roof of the paracœle (lateral ventricle). In most animals at two places, and in man and apes at three, the proper nervous wall disappears (or in some cases, perhaps, is never formed), leaving the endyma and the pia in contact. The membranous area so constituted is a *tela*. The roof of the metacœle is the *metatela (tela choroidea inferior)*; Fig. 59 and Vol. VIII., Figs. 4684, 4710, and 4711; that of the diacœle is the *diatela* (Fig. 59 and Vol. VIII., Figs. 4711 and 4751. In man and apes a zone of the paracœlian floor is a membranous *paratela*. Fig. 61 and Vol. VIII., Figs. 4750 and 4751.

§ 11. *The Plexuses.*—At several localities in the brain the pia forms vascular quasi-intrusions (choroid plexuses) into the cavities, carrying before it, however, the endyma lining those cavities, so as to be, strictly speaking, excluded therefrom; see Figs. 60, 61, 62, and 418; also Vol. VIII., Figs. 4708, 4709, 4710, 4740, 4745, 4749, and 4751.*

§ 12. *Points Illustrated by Fig.* 416.—A. The existence of two layers of dura in the cranium, the one corresponding with the periosteum of the spinal canal, the other with the dural sheath of the myel, Fig. 413, *a*.

B. The existence of two layers of arachnoid—an ental or pial, and an ectal or dural.

C. The propriety of regarding the so-called subdural space as an intrarachnoid space, analogous with the serous sacs in other parts of the body; see § 24.

§ 13. *The Dura.*—This mononym is rapidly replacing *dura mater* and the German *harte Hirnhaut;* see § 6, note. As shown in Figs. 414 and 415, and in Vol. VIII., Fig. 4687, the cranial dura is apparently a single sheet, dense, strong, fibrous, and unyielding, lining the bones and constituting their ental periosteum. But a closer examination detects two layers, an ectal and an ental, which gradually separate in the cephalic part of the cervical region, and in the spine maintain diverse relations, the one with the canal, the other with the myel.

§ 14. *The Theca.*—The ental or myelic portion of the spinal dura constitutes a fibrous tube, the theca. It is considerably longer and larger than the myel itself, and separated from the periosteum, constituting the wall of the canal by venous plexuses and much areolar tissue. The cavity between the pia and the dura is occupied by cerebrospinal fluid (cœlio-lymph), and is divided by the curtain-like arachnoid into the spaces subdural and subarachnoid. Within the latter the myel, closely covered by pia, is suspended, being kept in position by a ligament on each side, *ligamentum denticulatum* (Fig. 413), which fixes it at frequent intervals to its sheath, and by the roots of the spinal nerves (Fig. 413, *f*), which cross the space from the surface of the myel to the intervertebral foramina.

§ 15. *The Epidural Space.*—In the spine, since there are two layers of dura, an ectal (periosteal) and an ental (myelic), the interval between them constitutes an epidural space. In the figures this is nowhere clearly shown, but it may be represented in Fig. 413 by drawing around the present ectal outline, the myelic dura, a second at a little distance therefrom; the interval would be the epidural space.

§ 16. Two questions naturally arise in connection with the epidural space.

1. Does it communicate with the subdural space? If so, where?

2. If not, what is the source of the liquid occupying the space, and what is its nature?

§ 17. *Points Illustrated by Fig.* 417.—A. The relation of the dura to the cranium as a complete lining of considerable thickness.

B. The relation of the falx and falcula, as mesal extensions of the dura, to the tentorium as a transverse extension.

C. The tent-like form of the tentorium, the lateral margins coinciding approximately with the long axis of

* Dr. Langdon informs the writer that the cut does not represent the original drawing quite fairly in some respects.

† On such diagrams the endyma ("ependyma" or lining of the cavities) may be represented by yellow or green.

* On the mode of formation of the rima (sometimes called choroid fissure) independently of the blood-vessels, see His, "Die Formentwickelung des menschlichen Vorderhirns," etc., Leipzig, 1889, pp. 694 and 712, as quoted by Cunningham, "Surface Anatomy of the Primate Cerebrum," 1892, p. 3.

the cranium, the intermediate portion rising toward the meson at an angle rapidly increasing from the occiput cephalad.

D. The inversion of the falcula as compared with the falx.

E. The general arrangement of the more prominent fibres of the falx; there is a marked divergence or radiation from about the place of intersection of the free margins of the falx and the tentorium.

F. The locations of the principal sinuses along the lines of attachment of the dural folds to one another or to the cranium.

G. The direction of the current in the principal sinuses:

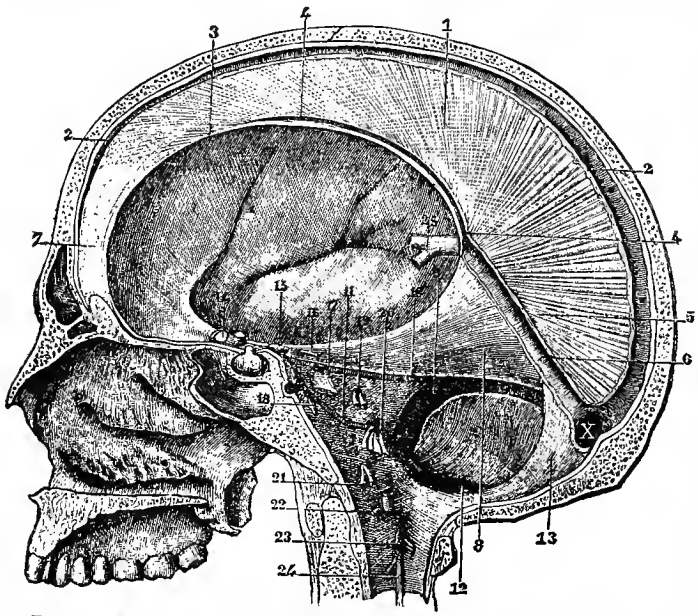

FIG. 417.—Mesal Aspect of Right Half of Medisected Skull retaining the Dura. ×.5. From Sappey (iii., Fig. 462); after Quain (iii., Fig. 129). Compare Fig. 759 in Vol. II. of this work.

Defects.—As usual, there is no indication of the change that occurs at or near the foramen magnum, by which the apparently single dura of the cranium divides into a true dura related to the myel (Fig. 413) and a spinal periosteum; see, however, Quain, iii., Fig. 182. The region of the postoccipital sinus (12) is so heavily shaded as to give the impression of its considerable width; as shown in the original of Sappey, this sinus is no larger than the subpetrosal; according to Browning (HANDBOOK, VIII., p. 242), this is merely a constituent of the irregular basilar plexus of venous channels. The vein of Galen (25) here joins the tentorial sinus at an angle of about 45°; really, as shown in Fig. 418, it curves about the rounded splenium and joins at nearly a right angle.

1, falx; 2, longitudinal sinus; 3, concave ventral margin of falx; 4, falcial (inferior longitudinal) sinus; 5, base of the falx where it joins the tentorium; 6, tentorial (straight) sinus or *s. rectus*; 7, cephalic, narrow end of falx, a little dorsad of the *crista galli* to which it is attached; ventrad of the line is a frontal (air) sinus, seen also in Fig. 4684; 8, right side of tentorium, sloping latero-ventrad from the attachment to the falx to the side of the cranium along the lateral sinus (9); X, the torcular, the place of confluence of the two lateral sinuses, the longitudinal and the falcial; 10, the superpetrous (superior petrosal) sinus; 11, the subpetrous (inferior petrosal) sinus; 12, postoccipital (posterior occipital) sinus; the arrows indicate the direction of the blood in the larger sinuses; the lateral sinus is continuous with the ento-jugular vein: 13, falcula (falx cerebelli); 14, optic nerve; 15, oculo-motor nerve; 16, trochlearis nerve; 17, trigeminus (trifacial) nerve; 18, abducens nerve; 19, facial and auditory nerves; 20, glosso-pharyngeal, vagus, and accessory nerves; 21, hypoglossal nerve; 22, 23, first and second cervical nerves; 24, cephalic end of the *ligamentum denticulatum* (see Fig. 413); 25, union of the velar veins to constitute the vein of Galen opening into the tentorial sinus (see Fig. 418).

in the longitudinal (2) and tentorial (6) (with the falcial, (4)) toward the torcular; in the lateral (9), toward the exit in the base of the skull at the jugular vein (4), in the superpetrosal and subpetrosal (10, 11) to the lateral.

H. The entrance of the supercerebral veins into the longitudinal sinus at the points indicated by the black spots in the course of the latter and at others not indicated; see Vol. VIII., p. 237.

§ 18. *The Tentorium.*—The cerebral region of the cranium is partitioned off from the region containing the cerebellum by a fold of the ectal layer of the dura, which, from its arched shape, is called the *tentorium (cerebelli)*. Its topographical relations with several of the sinuses are described by Browning, Vol. VIII., pp. 241-242, and indicated in Figs. 417 and 418.

The tentorium exists in most, if not all, mammals, but not, so far as the writer is aware, in other vertebrates; in the Carnivora it is ossified.

§ 19. *The Falx.*—From the cerebral side of the tentorium extends cephalad a mesal duplicature of the dura, the falx, well named from its sickle-shape; Figs. 417 and 419. The narrower cephalic end is attached to the *crista galli*. The distance between the free margin of the falx and the callosum increases cephalad. The relations of the falx to the longitudinal and falcial sinuses are shown in Figs. 417 and 418.

§ 20. *The Falcula.*—This name (wrongly printed *falcicula*) was proposed by the writer as a mononym for *falx cerebelli*, designating the mesal fold of dura which extends ventrad from the tentorium to the *foramen magnum*, where it bifurcates. It is vaguely shown in Fig. 418, 5, more clearly in Fig. 417, 13.

§ 21. *The Fontanels* (*Fr. fontanelles*).—These are the intervals between the corners of the infantile parietal bones before these corners have formed sutural union with the adjacent bones. There are six fontanels, two mesal and two pairs of lateral. The lateral, at the cephalic and caudal angles of the ventral border of the parietal bone, are small, irregular, and of comparatively little interest. The two mesal fontanels are at the ends of the sagittal suture; their more common designations, *anterior* and *posterior*, may appropriately give place to *prefontanel* and *postfontanel*.

§ 22. *Analogy of the Fontanels with the Telas.*—The structure of a tela was described in § 10. But since, in mammals at least, the telas are always more or less closely adherent to adjacent parts, and their margins are easily detached, their relations are sometimes not clearly appreciated. But if an infant or fœtal cranium be divided across the prefontanel diagonally, so as to include either parietal bone and the opposite frontal, the cut edge will present three layers, viz., an ental, the dura, representing the endyma; an ectal, the pericranium, representing the pia; an intermediate, the bone, representing the nervous parietes. At the fontanel this third element is absent, and the conjoined dura and pericranium contribute a membranous area quite comparable with a tela and available for illustration thereof.

A defect in the analogy is this: The cranial bone is of nearly uniform thickness, and thins out at the margin of the fontanel. But in the brain, although the immediate margins of the telas may be thin, the general parietes are commonly very massive, and there is usually a parallel zone specially differentiated, *e.g.*, the habena.*

§ 23. Points illustrated by Fig. 418 as to Meninges and Vessels; other points are indicated in Vol. VIII., pp. 121-123.

A. The degree of retention of the dura in this specimen is greater than with any brain ever seen or heard of by the writer. The brain was most skilfully removed, according to the writer's directions, by Professor W. C. Krauss, a former student; see p. 117, § 33.

* It is proper to add that, although this analogy between the telas and the fontanels had already occurred to the writer, he was reimpressed with it on listening to an admirable lecture upon the anatomy of the brain by Professor D. K. Shute, at the Columbian Medical College, Washington, D. C., December 16, 1889.

B. The existence, in the caudal three-fifths of the cerebrum, of a distinct and considerable mesal depression, containing the longitudinal sinus, so that here the retreating surface of the dura is seen beyond its dorsal cut margin ; presumably this corresponded with a mesal thickening of the cranium.

C. The distinctly sickle-shape of the mesal extension of the dura between the two hemicerebrums, whence its name, *falx*.

D. The non-correspondence of the width of the falx with the area dorsad and cephalad of the larger part of the callosum.

E. The location, form, and extent of the medicisterna (*cisterna ambiens*), the irregular space between the cerebellum, the splenium, and the geminums, roofed by the arachnoid and tentorium.

F. The location, form, and extent of the ventricisterna (*cisterna intercruralis*), between the crura, the pons, and the tuber*(*tuber cinereum*), infundibulum and hypophysis. It forms a very deep indentation of the ventral outline of the brain, corresponding with the cranial or mesencephalic flexure ; Vol. VIII., p. 112, § 16. It is bridged by the arachnoid, following substantially the line of the dura, and thus includes the arteries of this region.

G. The location, extent, and form of the postcisterna (*cisterna magna cerebello-medullaris*), the interval between the dorsum of the oblongata, the cerebellum, and the adjacent portion of the cranium, or strictly the ectal layer of arachnoid in that region, represented by the black line marked 10 ; see Figs. 420, 421.

H. The location of the metapore (Foramen of Magendie), the orifice in the metatela (*tela choroidea inferior*), constituting the roof of the metacœle or metencephalic portion of the "fourth ventricle." The metapore is thus a direct orifice of communication between the metacœle, one of the encephalic cavities, and the postcisterna, a part of the subarachnoid space ; see Figs. 422, 423, and § 28, note. In this specimen its relations are complicated by the postcerebellar artery, a loop of which lies just dorsad of it ; see under Defects.

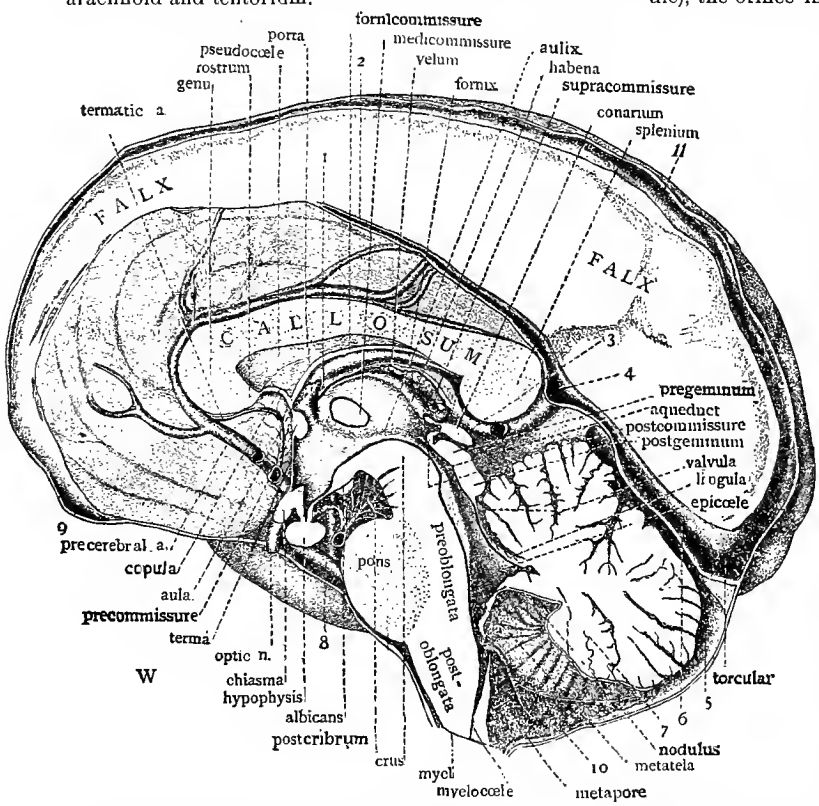

FIG. 418.—Mesal Aspect of the Right Hemiencephal of an Adult White Man. 376 × .65. 1, antiplexus; 2, falcial sinus ; 3, right velar vein ; 4, orifice of Galen's vein into the tentorial sinus ; 5, falcula or "cerebellar falx ;" 6, tentorial sinus ; 7, uvula, a mesal division of the cerebellum ; 8, tuber ("tuber cinereum") ; the line seems to stop at the artery, but should reach the thin floor of the diacœle just caudad of the hypophysis; 9, ventral end of the falx ; 10, cut edge of the ectal layer of the arachnoid ; the line is too heavy and should be white instead of black ; at a point between the lines from 6 and 7 it becomes attached to the cerebellar piarachnoid ; 11, longitudinal sinus.

Preparation.—This figure is reduced from the writer's Fig. 4711 in Vol. VIII. In addition to what is there recorded it should be said that the figure represents a combination of the more perfect portions of the two mesal aspects, and the left more than the right. The dura has since been removed, excepting its ventral margin. The left half has been transected through the mesencephal ; the dorsal portion of the right hemicerebrum has been sliced off to the level of the paracœle, but secured in place with long pins.

Defects.—Although one of the purposes of the preparation of the figure was to indicate the relations of the dura to the brain, the word is omitted altogether. *Falx* designates its mesal extension between the halves of the cerebrum, as shown in Figs. 415 and 417. Along the longitudinal sinus (11) should be indicated the points of entrance of the supercerebral veins (see Vol. VIII., Fig. 4684). The sinus, dorso-caudad of the cerebellum, between the torcular and the point marked 4, should be named *tentorial sinus*. On the precerebral artery, dorsocephalad of the chiasma, are two orifices. The more caudal, at the root of the termatic artery, is caused by the removal of the left precerebral (see § 23, P). The more cephalic, between the lines from *copula* and *aula*, should be omitted, together with the intervening depressed area ; they represent an accidental excavation of the artery. The arteries in the ventricisterna, the interval between the pons, the crura, and the tuber, are vaguely and inaccurately shown (see § 23, F). The postcerebellar artery (undesignated but lying between the lines from *metapore* and *metatela*) looks as if it begins in the metapore (see, however, § 23, H). The pia is nowhere distinctly represented. The black line marked 10 is the ectal layer of the arachnoid (see Fig. 421) ; the ental layer, in contact with the cerebellum, may be recognized ; they unite just dorsad of the line from 7. The curved white line about midway between the callosum and the fornicommissure is due to an error ; the surface of the hemiseptum forming the lateral wall of the pseudocœle should be uniformly shaded.

I. The location of the postcerebellar artery. This is not named on the figure and is imperfectly shown. The central portion, from its origin at the vertebral, is invisible here, but shows in Figs. 420 and 423. Just at the side of the metapore it turns sharply upon itself, forming a loop, somewhat as in Fig. 420, but in the present figure the peripheral portion of the artery alone is seen, and looks as if it began in the metapore. The two principal divisions are as here represented. There is apparently considerable variation in the course and subdivision of this vessel.

J. The length of the longitudinal sinus, equalling nearly the greater curvature of the cerebrum ; its cephalic end was probably not quite reached.

K. The presence of the falcial sinus (2) along the ventral, free margin of the falx. This is said to be often wanting ; see Vol. VIII., p. 129, § 59, and p. 241. The writer suggests that the alleged absence of this sinus in the fœtus may be due to its non-detection.

L. The straight course of the tentorial sinus in line with the falcial, along the ventral margin of the caudal fifth of the falx, where the latter is continuous with the tentorium (Fig. 417, 8). The tentorial sinus is not named or otherwise designated on this figure, but in Fig. 417 it is numbered 6 ; it is also called straight sinus or *sinus rectus*.

M. The junction of the mesal longitudinal and tentorial sinuses at the torcular (Herophili). The course of the lateral sinuses thence is indicated in Fig. 417.

N. The location of the right velar

* In previous articles in the HANDBOOK the tuber cinereum was called torus ; but the writer's attention has been called to the use of *torus*, either alone or in combination with *semicircularis*, to designate mesencephalic elevations in fishes ; hence it will be better to retain the substantive element of the original name.

vein (3) between the splenium of the callosum and the conarium, and its junction with its opposite at the point indicated by the circular spot at the edge of the spleninm, just in line with the dotted line from that word. The two velar veins form the short vein of Galen.

O. The brief course of the vein of Galen about the splenium, and its entrance at 4 into the tentorial sinus, at the place of continuity of the latter with the falcial when this is present.

P. The location of the right precerebral artery (anterior cerebral). Branches of this are seen dorsad and cephalad of the callosum. The main trunk extends dorso-cephalad from the chiasma. The dark spot between the dotted lines leading from the words *terma* and *precommissure* represents the junction of the two precerebral arteries at the meson; in some cases they are separated by a considerable interval and communicate by a slender precommunicant artery. Here, however, they unite by their full width and again diverge.

Q. The origin of the termatic artery from the place of junction of the two precerebrals; its course, parallel with the terma and copula, then around the genu at least to the dorsum; its short branches to the terma and adjoining parts of the hemicerebral meson.

R. The location of the postcerebral artery. The beginning of this, severed from the basilar, is represented by the circular spot between the hypophysis and the convexity of the pons. From it are seen small arteries entering the crura as described by Browning, Vol. VIII., p. 235. For the two large vessels represented in the ventricisterna, see under *Defects*.

S. The location of the aulix, the **S**-shaped furrow on the mesal surface of the thalamus ventrad of the medicommissure. This, originally called *sulcus Monroi* by Reichert ("Der Bau des menschlichen Gehirns," Taf. ix., i.) is held by Minot ("Human Embryology," pp. 611, 680) to represent the fundamental division between the "dorsal and ventral zones of His."

§ 24. *The Arachnoid.*—The word *arachnoid* is derived from the Greek ἀράχνη (signifying either a spider or a spider's web), and εἶδος (form or likeness).* Our knowledge of the arachnoid is even less complete and satisfactory than that of the dura and pia, and there are direct contradictions in the accounts by different anatomists which the writer has as yet been unable to reconcile.

As stated by Langdon (1891), Bichat described (1802, 1813) the arachnoid as a serous, shut sac, conforming in all essential particulars with the serosa of the other cavities. But most recent writers follow Kölliker (1860) in denying the existence of a parietal layer in contact with the dura, and Tuke regards (1882) even the visceral layer as merely an element of the pia.

§ 25. On February 17, 1888, the writer made and recorded the following observation upon a child, still-born, at term, No. 2258: In removing the parietal dura, a delicate membrane separated from it more or less easily in different localities on the two sides; it was observed also by the writer's colleague, Professor S. H. Gage. Although this distinctly indicated the existence of a parietal (ectal) layer of arachnoid, at that time the writer supposed the subject, Meninges, would be treated by another, and was, moreover, then fully occupied with the articles already undertaken; hence the observation was not made public.

§ 26. On December 29, 1890, Dr. Langdon's paper (1891) was presented before the Association of American Anatomists. He records observations made upon two children, at term, and one adult. His summary is as follows:

"The arachnoid is a true shut sac, similar in structure and function to the serosa of the other great cavities. Its parietal layer is easily separable from the dura at the vertex in the fœtus and young infant, but practically inseparable in this region in the adult. At the base of the skull it is demonstrable as a separate membrane, even in the adult. To assert that the parietal layer of arachnoid is absent because its subepithelial connective tissue has fused at the vertex with the dura (connective tissue), is as incorrect as to describe the great omentum as one layer of peritoneum, because its original four layers have become matted and adherent."

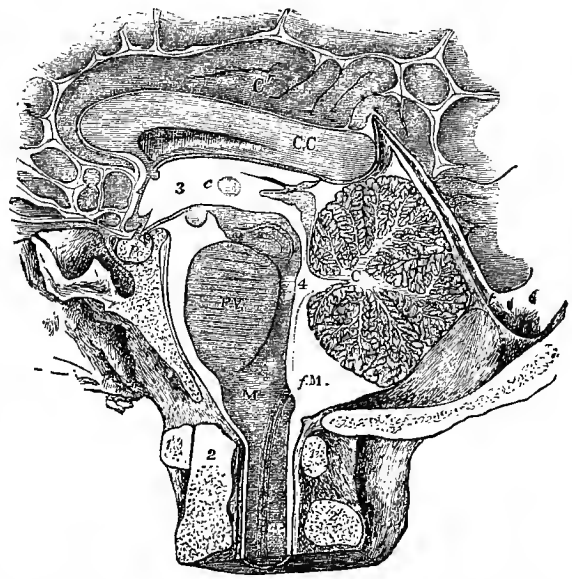

FIG. 419.—Medisection of the Cerebellum and Adjacent Parts. From Key and Retzius (Taf. viii., vii., Fig. 1); after Quain (iii., Fig. 131), reduced and somewhat modified. Compare Fig. 6, and Vol. VIII., Fig. 4684. 1, 1′, Atlas vertebra; 2, 2′, axis vertebra; 3, diacœle (third ventricle); 4, epicœle, the cephalic or cerebellar portion of the "fourth ventricle;" C, cerebellum; C.C., callosum; C′, callosal gyrus; M, postoblongata; P. V., pons; X, falcula (falx cerebelli) *c*, medicommissure; *c.c.*, just dorsad of (behind) the myelocœle (central canal of the cord); *f.* M., metapore; *p*, hypophysis; *t*, torcular.

Preparation.—A blue mass was injected into the spinal subarachnoid space; the head was then frozen and medisected. The original includes the mesal aspect of the entire head, less the integument and mandible. The true encephalic cavities and the subarachnoid spaces are colored, so only the actual mesal parts appear.

Defects.—In the original there is no indication of the arachnoid, although the circumscription of the subarachnoid space was the very feature supposed to be illustrated. Should it be claimed that the arachnoid is sufficiently indicated by the ental boundary line of the dura, the answer would be that, although in places the two meninges may be in contact, they are not in all; furthermore, as distinctly shown upon Taf. vi. of the same work, in Fig. 4711 of Vol. VIII., and in Figs. 420 and 421 of this volume, there is a point near the crest of the cerebellum (nearly opposite *t*) where the arachnoid (or its ectal layer) leaves the cerebellum and passes directly to the dura at the *foramen magnum*. There is no boundary between the metepicœle (fourth ventricle) and the subarachnoid space; even if, as in other cases, the membranous roof of the metacœle (metatela) adheres to the caudoventral surface of the cerebellum, the plexuses and the endyma constituting its ental surface must end somewhere; see p. 119, § 49.

The copy in Quain (9th and 10th eds.) omits the face and most of the cerebrum. Since the cavities are not colored, they appear as white areas without perspective, as if the preparation were a thin mesal slice. Most unfortunately, probably through some defect in execution, there is left a clear line between the conarium and the splenium, as if there were a passage from the diacœle (third ventricle) to the irregular subarachnoid space between the splenium, conarium, pregeminum and cerebellum. This is altogether misleading, for, as shown in Fig. 700 and on 4684, 4711, and 4718, and stated on p. 123 of Vol. VIII., the diacœle is completely circumscribed at that point by the endyma reflected from the velum upon the conarium. In the present copy this defect has been remedied so far as it could be by uniting the conarium and splenium so as at least to block the passage; but it should be remembered that it is closed not by nervous tissue but membranes. The editors of Quain have represented the missing metatela by the dotted line from near the number 4 to near the abbreviation *f.* M. A continuous line would have been more appropriate, and separated farther from the metacœlian floor; that could not be changed in the present copy, but the interval representing the metapore (foramen of Magendie) has been enlarged somewhat. Finally, the falcula (falx cerebelli), which was unmarked in Quain, is here designated by a cross (x).

§ 27. During the preparation of the present article the writer has verified the correctness of the previous obser-

* The open-meshed disks of the common garden-spiders, *Epeira*, *Argiope*, etc., are not comparable; rather the compact glazed sheet constructed by one of the house-spiders (*Tegenaria*) which will hold water, or the still more substantial nest of the water-spider (*Argyronetra*), which is like a stationary diving-bell and retains the air placed under it against considerable pressure.

vation as to the presence of an ectal or dural layer of arachnoid, and has noted its reflection upon the carotid and vertebral arteries to become continuous, presumably, with the ental, pial, or visceral layer. But no such reflection occurs at the nerve-roots unless at some depth within the foramens of exit, and this point the writer has as yet not had time to determine.

§ 28. Points Illustrated by Fig. 419.—A. The complete circumscription of the true encephalic cavities, excepting at the metapore.

A. The non-communication of these cavities with the pseudocœle (fifth ventricle).

C. The presence of considerable, irregular intervals, snbarachnoid spaces, or cisternas, between the pia and the arachnoid.

D. The continuation of the largest of these, *postcisterna*, between the cerebellum, postoblongata and occipital part of the craniun, with the spinal subarachnoid space.

E. The relation of the falcula (falx cerebelli) to the mesal portion, vermis, of the cerebellum; in Fig. 418

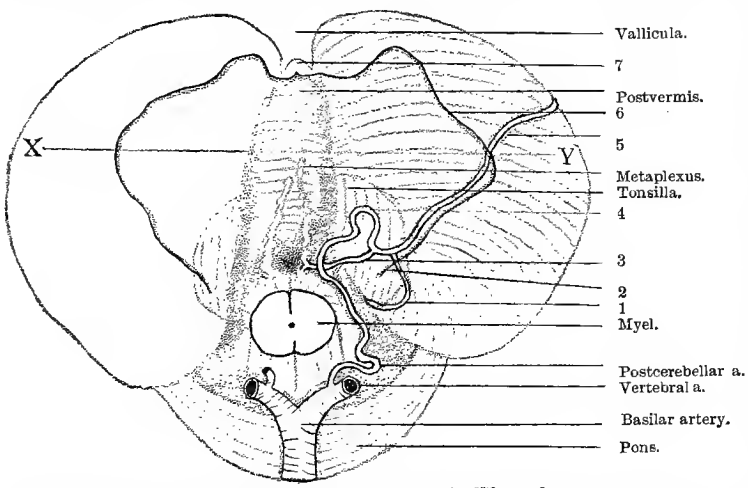

FIG. 420.—Caudal (lower) Aspect of the Cerebellum, etc., No. 376; × .9.

Preparation.—Through the kindness and skill of Dr. W. C. Krauss (a former student, now Professor of Pathology in the Medical Department of Niagara University in Buffalo, N. Y.), the brain was received fresh and in the dura. The cavities were injected with alcohol; the arteries first with alcohol and then with the starch mixture (p. 115, § 24). The alcohol passed through the metapore into the postcisterna and thoroughly preserved all the parietes; it had access also about the myel, where the arachnoid was cut in removing the brain. The ectal layer of the arachnoid was cut away along the line of its attachment.

Defects.—The perspective of the postoblongata is defective. The metapore is vaguely indicated and few of the vessels are shown. Of the lobes only the tonsillas are outlined. The flocculi and nerve-roots are omitted, also the rimulas (interfoliar crevices) on the left side. The most serious defect is the non-indication of the dorsal limit of the endyma which presumably accompanies the metaplexuses.

1, 3, Branches of the postcerebellar artery, the former passing between the cerebellum and the oblongata, the latter apparently supplying the corresponding metaplexus.

2, 6, Edge of the ectal layer of arachnoid bounding the area whence it had been cut away.

4, Loop of postcerebellar artery, an example of its tortuous course.

5, Main trunk of the artery near where it reaches the crest of the cerebellum; its branches are omitted.

7, Mesal ridge formed by the vein which divides into a right and left branch upon the caudal surface; the arachnoid here forms a somewhat sharp angle.

this is obscured by the fact that part of the left lateral lobe remains.

§ 29. *The Cisternas.*— At several regions the ental layer of arachnoid is separated from the pia by considerable spaces, called cisternas by Key and Retzius, 1875, p. 93.* They are enumerated and briefly described by Browning, Vol. VIII., p. 244.

§ 30. *Points Illustrated by Fig.* 420.—A. The general appearance of this aspect of the cerebellum together with the oblongata and pons; in Fig. 4177 these two parts were omitted.

B. The extent of the postcisterna (*cisterna magna* or *c. cerebello-medullaris*) upon about one-half the entire caudal aspect; there is, however, considerable variation in this respect.

C. The definite dorsal and lateral limitation of the postcisterna, although the boundary line is undulating and asymmetrical.

D. The lack of ventral boundary of the cisterna; the ectal layer of the arachnoid is attached to the dura so that this cisterna is continuous with the spinal subarachnoid space.

E. The union of the two vertebral arteries to form the basilar.

F. The origin of the postcerebellar arteries from the vertebrals near their junction.

G. The length and course of the postcerebellar artery, and the tortuous course of its central portion.

H. The passage of a branch of the postcerebellar artery mesad toward the metapore, apparently supplying the metaplexus.

I. The extension of the metaplexuses dorsad from the metapore upon the cerebellum.

§ 31. *The Postcisterna.* — Notwithstanding the presumption that all the cisternas form a continuous series, the writer's observations, up to the present time, compel him to regard the space in the angle between the cerebellum and the oblongata as presenting an important peculiarity, viz., as lying, not between the pia and the visceral arachnoid, but between two layers of the latter. The facts upon which this view is based cannot be detailed here. The view is indicated upon Fig. 421.

The writer is aware of the difficulties involved in its acceptance; without question, the postcisterna communicates on the one hand with the true encephalic cavities through the metapore, and on the other with the spinal subarachnoid space; its free communication with the other cisternas, although commonly accepted, seems to the writer not yet clearly demonstrated.

§ 32. *Points Illustrated by Fig.* 421.—A. The usual relation of the meninges in these respects, viz., the independence of the dura; the adhesion of the pia to the brain-substance; the dipping of the pia into the narrow depression at either side of the vermis as a vascular fold; the adhesion of the arachnoid to the pia over most of the cerebellum, so as to constitute a piarachnoid; Vol. VIII., Fig. 4687.

B. On the caudal aspect of the cerebellum, the formation of a considerable space, the postcisterna, by the separation of an ectal layer of the ental or visceral layer of the arachnoid.

§ 33. *The Metapore* (*Foramen of Magendie*).*—Historical. On December 18, 1826, before the Académie des Sciences, Magendie read the second part of his second memoir upon the liquid contained in the spinal canal and the cavities of the brain. It was published in the *Journal de Physiologie* for January, 1827, Tome vii., pp. 1–29.

On pp. 21 and 22 Magendie declares that the fourth ventricle of the brain communicates with the subarachnoid space of the spinal canal through an orifice in the roof of the ventricle. He adds that, in the human adult, this is a constant condition easy to verify, and briefly describes the method of exposing the brain for the purpose.

* Admitting that most of the cisternas do lie between the arachnoid and the pia, as commonly described, the writer's later observations lead him to regard the postcisterna as between two layers of the ental arachnoid itself; see Figs. 420 and 421.

* This portion of the article is based upon a paper by the writer, read before the Association of American Anatomists, at Princeton, December 29, 1892. See Amer. Neurol. Trans., 1893.

Magendie designated the orifice as *entrée des cavités du cerveau* or *entrée des ventricules cérébraux*. In 1855 Luschka published a description and figure of the orifice, which he re-named *foramen Magendii*. In the present article, as in Vol. VIII., p. 123, these and various other polyonyms are replaced by the mononym *metapore*, Latin, *metaporus*, signifying an orifice in the metatela, the membranous roof of the metacœle, the cavity of the metencephal.

§ 34. Most later anatomical writers have admitted the existence of the metapore, but the descriptions are commonly brief and the figures unsatisfactory. That by Key and Retzius is suspiciously symmetrical, though it is copied by Schwalbe; Henle's (Fig. 423) is more natural; the best figures and the fullest description are those of Carl Hess, 1885, but no figure has the appearance of having been based upon a photograph.

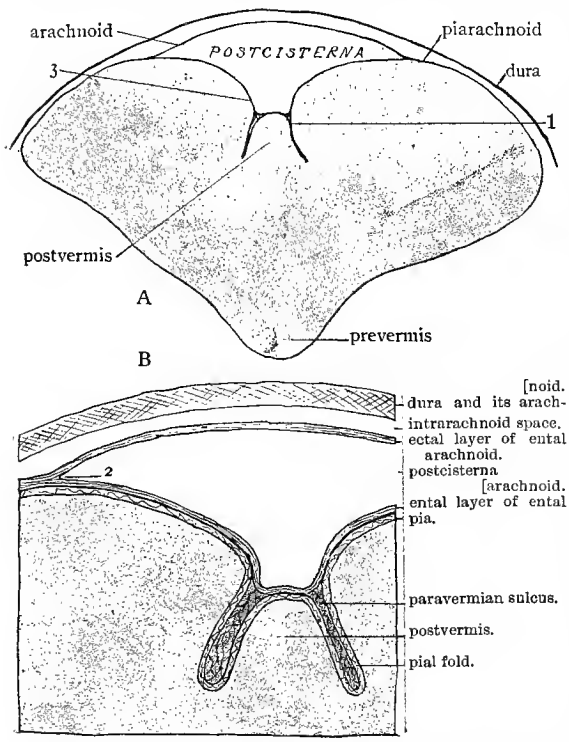

FIG. 421.—Sections of the Cerebellum and Postcisterna; semidiagrammatic.

A. Dorsal (cut) surface of the ventral portion of the cerebellum, together with the adjacent dura and the large "subarachnoid space," postcisterna, commonly called *cisterna magna* or *c. cerebello-medullaris*. At the meson appears the postvermis, separated by the paravermian sulci (1) from the large lateral lobes; 3 is the ental layer of the arachnoid. The meninges are here represented by lines only.

B. Enlargement of the meso-caudal region of A. The meninges are here represented by zones conventionally shaded; 2, the place of junction of the two layers of the ental arachnoid at the margin of the postcisterna.

Preparation.—An adult cerebellum (2891) was divided at a plane corresponding with the line X—Y in Fig. 8, so as to separate the dorsal two-fifths; on Fig. 4711 (Vol. VIII.) the plane of section would be indicated approximately by a line across the unshaded (cut) surface connecting the points where the dotted lines from the words *nodulus* and *epicœle* intersect the margin of that surface; as seen in Fig. 420 it passes dorsad of the plexuses. The ectal layer of arachnoid is represented as the continuous caudal boundary of the postcisterna, while in Fig. 420 it is supposed to have been trimmed closely along the line of its depression from the ental layer 3.

Defects.—For readier comparison with Fig. 421 the figures should have been inverted so as to have the postcisterna nearer the reader. In B the postcisterna is enlarged two diameters, but the several zones representing the meninges are disproportionately widened, and their shading is conventional for discrimination only, and not for the indication of histological structure. The ectal or dural layer of arachnoid was inadvertently omitted, and there is no indication of the two layers of the dura itself. The numerous rimulas and interventing foliums that were divided in the section are not indicated, and the usual relations of the pia and arachnoid to each other and to narrow encephalic depressions generally are illustrated only at the paravermian sulci.

§ 35. The metapore is regarded as an artificial orifice by Kölliker, 1884, p. 248, but apparently on *a priori* embryological grounds and without a personal examination of carefully prepared adult brains. An orifice in the metatela is shown by Reichert (1859) in a transection, Taf. ii., Fig. 14; the description, p. 113, merely states that the roof is incomplete, but in the *Résumé*, p. 185, he distinctly holds that any orifice in this region is artificial.

Gegenhaur (1888) admits the usual presence of the metapore (p. 819), but adds that it is sometimes absent, as in his Fig. 522.

§ 36. In 1884 (Cartwright Lectures on "Methods of Studying the Brain," *New York Medical Journal*, April 26, p. 458), the writer expressed doubts as to the existence of the metapore upon the following grounds:

1. Its absence in the cat and other animals examined.
2. Its morphological improbability, in view of the assumed conditions expressed in the phrases *endymal continuity* and *cœlian circumscription*.
3. The observed readiness with which membranous walls and adhesions are ruptured in the customary manipulations of the brain.

The paper of Hess (1885) and the possession of more perfect material, led to a re-examination of the subject. Several preparations were made and photographed (negatives 164 and 592). In a paper (1886), while reaffirming the unbroken continuity of the metatela in the cat, the writer stated that in man there is a mesal aperture approximately rhomboidal in outline, and about 5 by 8 mm. in diameter.

In 1889, in the article, "Gross Anatomy of the Brain," in the REFERENCE HANDBOOK, upon the supposition that a special article upon the meninges would be prepared by another, the writer restricted himself to indicating the location of the metapore upon a medisected brain, Fig. 4711 (this volume, Fig. 418), and to remarking, page 122, § 60, "that the metapore undoubtedly exists in man, though not, perhaps, in other vertebrates." The qualification was due to the conditions observed in a chimpanzee brain, but as this had been medisected no final conclusion could be derived from it.

§ 37. Notwithstanding the above declaration upon the part of one who at that time had been an anatomist for thirty years, in Minot's "Human Embryology" (1892), neither of the terms, foramen of Magendie or metapore, is used, and the whole subject is apparently disposed of in the following passages (p. 676):—"Several writers have thought that the membrane was broken through at certain points, but it probably is really continuous throughout life. The fourth ventricle is to be regarded, then, as an expansion of the central canal permanently bounded by the original medullary walls."

The writer infers that Minot follows Kölliker in regarding the almost unanimous testimony of anatomists as inadequate to outweigh the presumption against the formation of an orifice in a pre-existing membrane; yet he describes (p. 262, Fig. 170), under the name of *oral plate*, a septum between the mouth and the pharynx of the human embryo which must disappear before those two divisions of the enteron can become parts of a continuous canal.

§ 38. Aside, however, from the desirability of dispelling embryological scepticism, the question of the presence or absence of the metapore involves so many and so serious considerations, zoological, physiological, psychological, and even philosophical, that the writer has recently re-examined all the specimens in the Museum of Cornell University, and has prepared two with which the possibility of artificial disturbance of the natural relations had been avoided.

As the result, the following proposition is submitted:

In the normal adult human brain there is a considerable orifice in the roof of the metacœle whereby the liquid of the encephalic cavities may escape into the postcisterna. The only cases of apparent absence are in the brains of two insane persons, one of them hydrocephalous; but as both of these brains had been medisected, no final conclusion should be based thereon.

§ 39. *Points Illustrated upon Fig.* 422.—A. The existence of a natural orifice in the membranous roof of the "fourth ventricle."

B. The simplicity of the form and relations of the metapore in this specimen. It is mesal, symmetrical, and oval.

C. The appearance of the metaplexuses just within the cephalic margin of the metapore with no such extension upon the cerebellum as is shown in Fig. 420.

§ 40. There is perhaps no point in gross anatomy wherein the result is more dependent upon the method; hence the procedures in the two cases where the orifice was last observed shall be described in detail.

§ 41. *Alcoholic Specimen, No.* 2655.—In the spring of 1890 the head of an adult man, with most of the neck attached, was received in a fresh condition. The brain was hardened in place by the continuous injection of alcohol through the arteries; Vol. VIII., p. 200, and this volume, p. 114. The calva and contained portion of the cerebrum were sawn off, and the face with the frontal portion of the brain separated from the neck, cerebellum, and occipital region of the cerebrum. This latter mass was kept in strong alcohol until December 19, 1892. On this date, with a thin saw newly sharpened, the left side of the head and neck was removed so as just to clear the myel (spinal cord) and leave the region of the metapore wholly inclosed between the untouched right lobe of the cerebellum and the remnant of the left lobe. With a very sharp scalpel, frequently dipped in alcohol, the larger part of the cerebellum was cut away; more of the cranium was sawn off, and the vertebral arches removed with nippers. During all these operations the thorough hardening of the soft parts had prevented any movement of the cranium upon the atlas. The remnant of the cerebellum was now peeled cautiously up from its pia, and the left half of the oblongata cut out. Upon the region where the metapore was supposed to open was now dropped a little soapy water; the point of a blow-pipe was directed at—*not pushed into*—the metacœle from the ventral side; on blowing gently, bubbles formed on the dorsal side, showing the passage of air through the metapore. This was done in the presence of six witnesses, most of them trained observers.

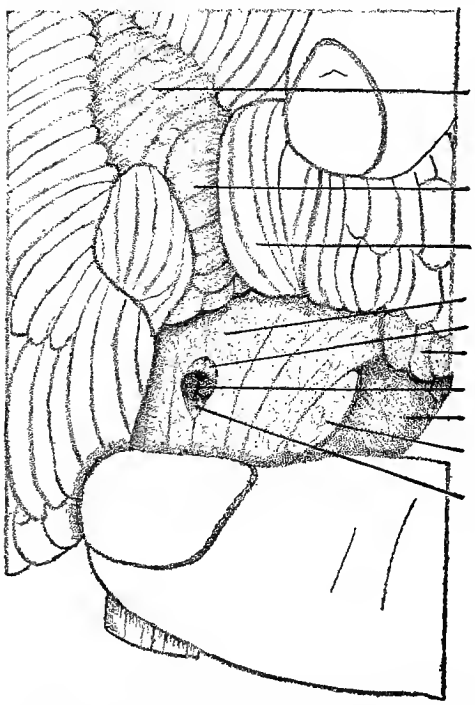

FIG. 422.—The Metapore (Foramen of Magendie) as Exposed by the Divarication of the Cerebellum and Oblongata. Specimen 318, Mus. Cornell University. × 1.

Preparation.—The brain of an adult Swedish* carpenter was removed with great care, according to the writer's method, *i.e.*, by dividing the calva sagittally at the left of the meson (Vol. VIII., p. 199), so as to avoid tearing membranous adhesions. The brain was supported on a bed of cotton; the arteries and the arachnoid extending from the cerebellum to the oblongata were cut away and the two parts held asunder with fingers so as to expose the region of the metapore. A photograph was then taken, upon which the drawing is based. After hardening, however, most of the cerebellum was cut away and another photograph taken of the reduced mass. The specimen and both photographs were shown at the meeting of the Association of American Anatomists, December 28, 1892.

Defects.—The right side of the cerebellum was displaced more than the left, giving rise to the marked obliquity. The metapore itself should be shown on a larger scale. The postcerebellar arteries are omitted; they do not appear distinctly in the first photograph, and no record was made of their locations. This is unfortunate, since in all the cases where they are preserved their relations to the metapore are close. Had more of the caudal aspect of the cerebellum been included, there might have been shown the line of attachment of the arachnoid at the boundaries of the postcisterna. The wavy lines on the dorsum of the oblongata hardly do justice to the vascularity of the pia covering that region.

*The left hemicerebrum is represented in Vol. VIII., Fig. 4778. Since that volume was published, and indeed after the pages of the present volume containing corrections of the article "Brain" therein, the writer has learned from a relative of the carpenter that he was not a Hungarian, as first stated, but a Swede.

The specimen was immersed in normal salt solution; the blow-pipe was so placed that the stream of air entered the metacœle. As soon as it was used the air collected in the postcisterna and gradually distended the arachnoid. At this first trial, in the presence of one witness, the arachnoid, notwithstanding its extreme delicacy, was absolutely unbroken, and when the cerebellum was permitted to tilt slightly cephalad, as in photograph 593, the distended sac presented a really beautiful appearance; during the subsequent manipulations a small rent was made at one margin where the arachnoid becomes attached to the cerebellum, so that the distention thereafter was less complete; it was observed, however, by several, that the air passed from the metacœle freely into the postcisterna, and the outline appears in the photograph, though vaguely.

It is essential in this connection to call attention to the fact that when the cerebellum was permitted to fall

Hitherto no instrument, even the comparatively safe syringotome (Vol. VIII., Fig. 4880), had approached the supposed location of the metapore. But when repeated trials had satisfied all interested that there was a natural communication, the syringotome was cautiously introduced, and the limits of the passage ascertained; then with fine scissors the left wall was removed. The cephalocaudal diameter of the metapore is more than 5 mm.; its transverse diameter would be about the same in the fresh state, but a knuckle of the right postcerebellar artery encroaches upon it.

In view of the ease with which natural membranous adhesions yield in poorly preserved brains, it is important to add that all the membranes in this preparation were firm and maintained their natural attachments so as to perceptibly resist separation. When it is added that the various operations upon the already hardened brain, which are briefly indicated above, consumed at least four hours, it may be believed that adequate precautions were taken against the production of any artificial conditions. Two stages of the dissection are represented in photographs 590 and 591.

§ 42. *Fresh Specimen,* 2971.—The head of an adult man was received fresh through the kindness of a former student, December 21, 1892. The neck and occipital region were sawn away from the rest of the head; the cephalic slope of the cerebellum remained attached to the cerebrum, but the larger part, containing the metapore, was undisturbed.

cephalad it was held by the arachnoid, even after removal from the liquid. Through the transparent membrane it could be seen that none of the parts included within it were upon the stretch.

Later the cerebellum and oblongata were removed from the remnant of cranium, the arachnoid was trimmed close to its attachment, and a second photograph (No. 594) taken. Then the specimen was hardened in alcohol and reduced to a more convenient size by cutting off most of the lateral lobes of the cerebellum.

There is no reason to suppose that any of the membranous attachments have been torn, but the presence of the metapore is unmistakable.

Even, therefore, if some doubt might be cast upon the reliability of the previously prepared specimens, the two whose preparation and examination have been here described, prove that Magendie and others have been correct in affirming the existence of a mesal orifice in the roof of the metacœle.

§ 43. The writer now feels justified, not only in reiterating the conviction which was expressed in 1886 and 1889, but in holding that upon the unbelievers now rests the burden of disproof. He is ready to demonstrate the metapore upon any fresh or well-preserved brain, and

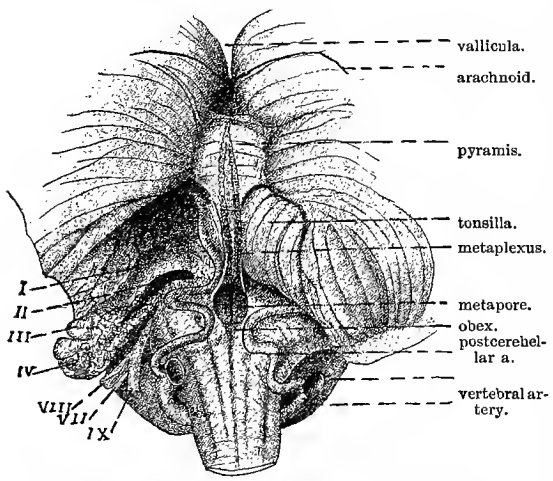

FIG. 423.—The Metapore (Foramen of Magendie) and Adjacent Parts nearly as represented by Henle. (Anatomie, iii., Fig. 232.)

Preparation.—In the absence of statement by the author, it may be said that the brain was probably removed in the usual way, and the cerebellum tilted cephalad so as to expose its caudal aspect and the dorsum of the oblongata. The left tonsilla was then cut out, exposing on that side the parts marked I, IX, and a continuation of the postcerebellar artery.

I, metatela (*velum medullare posterius*), its lateral portion; II, lateral recess of the metepicœle (fourth ventricle) opened by the removal of part of the metatela; III, flocculus; IV, epiplexus (*plexus choroideus lateralis*); see Vol. VIII., Fig. 4702; VII, VIII, IX, cranial nerve-roots.

Changes.—The boundary line of the tonsilla has been made more distinct than in the original. In the upper part has been introduced a line to represent approximately the line of attachment of the arachnoid, constituting the dorsal boundary of the postcisterna. (See Fig. 420.)

Defects.—The margins of the metapore are too sharply defined; this is, perhaps, unavoidable when the parts are upon so small a scale; it cannot be said to bear either way upon the question of the naturalness of the orifice, for the effect of tearing a tough membrane like the metatela would be to leave ragged edges. The relations of the plexuses and accompanying strip of metatela are inadequately indicated, and the writer regrets his present inability to elucidate them. The postcerebellar arteries are represented as if distributed only between the oblongata and cerebellum, and between the lobes of the latter. (Compare Fig. 420.)

will maintain its normal existence in the human adult until there are produced several otherwise normal brains presenting a continuous metacœlian roof.

§ 44. *Points Illustrated by Fig.* 423.—A. The admission of the normal existence of the metapore in the adult by so expert an anatomist as Henle.

B. The attachment of an extension of the metatela from the cephalic border of the metapore upon the uvula and pyramis of the cerebellum.

C. The extension of the metaplexuses upon the thus everted ental aspect of the metatela, whereas in the specimen represented in Fig. 420 they barely appeared at the margin.

D. The topographical relation to the metapore of the contorted postcerebellar arteries.

E. The relation of the flocculus to the lateral recess. See Vol. VIII., Fig. 4720.

§ 45. But while the main fact may be regarded as demonstrated, there are many subordinate points upon which our information is far from satisfactory.

§ 46. It is evident that there are two different arrangements. The simpler is apparently the less common. It exists in specimens 318, 376, 706, 2347, and 2870.

Here, as in Figs. 418 and 422, the metatela is readily separable from the overhanging cerebellum, excepting, of course, at the cephalic margin, where its two constituents, the pia and the endyma, are continuous with the same membranes on the ectal and ental surfaces, respectively.

In this kind the plexuses on the ental surface of the metatela appear, if at all, only just within the cephalic margin of the metapore.

In the second kind the metatela adheres closely to the cerebellum, the two apposed layers of pia not being separable; thus the cephalic wall of the metapore appears to be the cerebellum itself; but the extension dorsad of the metaplexuses shows that it is truly the metatela. As yet the writer has been unable to determine the precise limit of the metatela. See Figs. 420 and 423.

§ 47. Since the metatela consists of two different membranes, the ental endyma and the ectal pia, we should know their exact condition at the margins of the metapore. An analogous case is the orifice of the oviduct, where mucosa and serosa become continuous.

§ 48. At what period of development does the metapore appear? From the extreme softness of new-born and fœtal brains, it is evident that artificial rupture of the delicate metatela may easily be produced. Probably the best results may be anticipated from the examination of specimens prepared by transecting the brain at the mesencephal (gemina and crura), and injecting the preservative gently but continuously caudad through the mesocœle or aqueduct, so as to fill the cavities and fix the membranous attachments.

§ 49. How is the metapore produced? Is there an absorption of material over a given area? or is a rupture accomplished by spontaneous mechanical agencies, the margins of the rent becoming rounded off later?

§ 50. What is the significance of the close topographical relations of the postcerebellar arteries? The length and tortuousness of these vessels can hardly fail to impress anyone who carefully studies the region in question.

§ 51. Does the cœliolymph (cerebro-spinal liquid) pass in both directions with equal facility?

§ 52. Is the non-formation or obliteration of the metapore a cause or merely a concomitant of idiocy, insanity, or hydrocephalus? Horsley has recorded (*Brain*, July, 1885, p. 238) a case of encephalocele where the metatela was a "strong, fibrous sheet," and there have been already referred to two insane brains, one of them also hydrocephalic, where there is at least room for doubting the presence of the metapore.

§ 53. Does the metapore exist in any other animals, especially in the anthropoid apes? If not, then its presence would constitute one of the rather small number of absolute distinctions of humanity. Although the chimpanzee brain in the Museum of Cornell University probably is the most perfectly preserved in the world, its medisection prevents us from relying implicitly upon it. So far as may be inferred, there was a metapore, the plexuses extending upon the caudal surface of the cerebellum as in the second kind already mentioned. On January 11, 1893, through the kindness of Superintendent A. E. Brown, of the Philadelphia Zoological Gardens, the writer received the body of a baboon in excellent

coudition.* The cerebrum was removed without disturbing the cerebellum. Air was blown gently at the aqueduct; the stream was immediately felt escaping at the *foramen magnum*. A blue liquid allowed to run into the aqueduct from a small glass syringe, with a minimum of pressure, also escaped at the foramen. On removing the tentorium there was recognized a small but distinct postcisterna (*cisterna magna*), full of the liquid. On carefully lifting the cerebellum there was found to be a metapore of the first kind. This observation has been confirmed upon two other Old World monkeys. †

§ 54. *What is the Use of the Metapore?*—Those who admit its existence have generally supposed that, during the vascular congestion attendant upon cerebration, the undue compression of the brain within its unyielding case is prevented by the transfer of the cœliolymph, first into the postcisterna, and then into the spinal subarachnoid spaces.

But while the non-osseous portions of the spinal canal might yield to an ental pressure, is there any evidence of the distensibility of the myelic theca? And would not any pressure adequate either to distend it or to compress the liquid, injure the myel itself or the brain, or rupture the arachnoid bounding the postcisterna?

§ 55. *Are there other Natural Communications between the Encephalic Cavities and the Arachnoid Space?*—According to Quain (iii., 126, 188), Merkel and Mierzejewski have described an actual cleft in the pia along the medicornu. But the writer is not able to learn that these observations have been confirmed by others, or that any photographs or figures have been published. For the present, therefore, in view of the negative testimony of other anatomists, and the results of his own repeated dissections and experiments, he is compelled to regard such clefts, when found, as artifacts, comparable with the orifices near the porta in an alinjected brain (Vol. VIII., Fig. 4742).

§ 56. More generally admitted is the existence of natural orifices at the tips of the lateral recesses of the fourth ventricle. These recesses, parepicœles, are shown more or less imperfectly in Vol. VIII., Figs. 4702, 4703, 4704, 4714, 4720, 2, and in this volume Figs. 58 and 423. From Fig. 4702 it will be seen that, in the embryo, the extremities of these recesses are closed. The presumption is, therefore, that they remain closed in the adult. It is true that they are usually—perhaps always—found open in brains removed and examined in the ordinary ways; furthermore, Hess has given (1885) a representation (Taf. xxix., Fig. 10), apparently faithful, of what seems to be the natural condition of the parts. Nevertheless, so great is the probability of artificial rupture of the pia by reason of its adhesion to the nerve-roots (a probability far greater than with the comparatively protected metatela), that the writer feels compelled to withhold his recognition of the orifices until the publication of more detailed descriptions and of figures based upon photographs.

§ 57. *Is there Direct Communication of the Subarachnoid Spaces with the Intrarachnoid (or Subdural) Space?*—Whatever view they adopt regarding the constitution of the arachnoid as a whole, most writers agree that the arachnoid covering the brain and myel is continuous, excepting for the capillary spaces about the nerve-roots referred to in § 27. Hence, while the cœliolymph may pass to and fro between the true encephalic cavities and the postcisterna through the metapore, and may thus enter the other cisternas (§ 31) and the spinal subarachnoid space, it is nevertheless confined thereto.

But Dr. Langdon (1891) holds that "at the base of the cranium there are two points where the visceral [ental] arachnoid is deficient, one on either side, in the 'bridge' of arachnoid which stretches across from the cerebellar lobes to the under [ventral] surface of the oblongata. These foramina measure about half an inch (12 mm.) in longitudinal diameter by one-fourth inch (6 mm.) transversely, and are crossed by three or four fibrous bands, the attachment of which to the edges of the openings produces a multiple crescentic appearance of their margins, which suggests the name, '*lunulate foramina*.'"

It will be noted that the location of these alleged lunulate foramina in the arachnoid corresponds with that of the ventral ends of the lateral recesses. Hence, on the one hand, if both are natural, the transfer of the cœliolymph from the true encephalic cavities to the arachnoid space is provided for; on the other, the relation of the nerve-roots to both the pia and the arachnoid renders both liable to rupture during extraction or manipulation of the brain. Hess (op. cit., Fig. 10, *ar.*) implies that the arachnoid was cut and reflected at this point.

* This is No. 2977 of the University Museum; the chimpanzee above mentioned is No. 265; it also was sent by Superintendent Brown; the preparation of the brain by continuous arterial alinjection is briefly described in the *Proceedings of the Amer. Assoc. Adv. Science*, 1885, p. 527.

† Through the courtesy of Dr. W. A. Conklin, formerly Superintendent of the Central Park Menagerie, the writer has been enabled to examine the brain of an adult Orang, No. 3082 of the Museum of Cornell University. All precautions against artificial rupture were taken. Air passed readily from the mesocœle into a large and distinct postcisterna through several orifices in the metatela; these orifices and the postcisterna were photographed May 24, 1893; Nos. 657–660.

MENINGITIS. Etiology and Pathology.—The cause of cerebro-spinal meningitis is nearly absolutely established. Bonome, of Padua, declares that the *diplococcus of pneumonia* may now be regarded as the typical cause of epidemic cerebro-spinal meningitis, but as the cause of exceptional cases there are found (a) another diplococcus, (b) the streptococcus pyogenes, (c) a short, thick bacillus like the typhoid bacillus (Neumann and Schäfer),

and (d) an encapsulated bacterium like the pneumobacillus of Friedländer (Netter).

Bonome discovered a sixth micro-organism in an epidemic near Padua. The disease developed itself independently of any pneumonia and with quite peculiar symptoms: rapid, almost simultaneous attack of many and especially of robust individuals with chill, pains in the joints and along the spinal column, uncontrollable vomiting, fever up to 43° C., violent trismus, opisthotonus, fixation of the pupils, etc. Death, which was the result in seven of sixteen cases, often occurred within ten hours.

Section showed abundant exudation, and in one case pus in the vicinity of the cerebellum; cloudy fluid, with pus and flakes of fibrine in the lateral ventricles; numerous ecchymoses of the pia, and hæmorrhage into the ventricles twice; hæmorrhages under the peri- and endocardium. The lungs and pleura were always free from fibrinous inflammation; but there was hæmorrhagic exudation in the parenchyma of the lungs, and in a few cases in this exudation, as well as in that of the meninges, Bonome found constantly large round or oval immobile micrococci isolated or united in chains.

Huguenin makes the following divisions in explaining the origin of meningitis in general:

1. *Hæmatogenous Meningitis.*—The micro-organisms reach the pia through the arterial blood-supply. These are the cases of meningitis which occur after or in the course of ulcerative endocarditis, typhoid fever, cholera, pneumonia, typhus, recurrent fever, variola, scarlatina, measles; traumatic and puerperal sepsis; finally, cerebro-spinal meningitis. In most of these diseases it is a case of infection of the brain with streptococci. The streptococcus meningitis certainly occurs after ulcerative endocarditis, typhoid fever, variola, scarlatina (in both the last cases usually from the ear), measles, traumatic and puerperal sepsis. Of obscure origin are the cases which develop in the course of acute articular rheumatism. In this connection it must be remembered that hyperpyresis is often mistaken for meningitis. In the pneumonia meningitis the pneumococcus of Fraenkel has been unmistakably demonstrated. The bacteria of epidemic cerebro-spinal meningitis have not yet been isolated with certainty. Fraenkel's pneumococcus has often been found. Weichselbaum has described also a bacillus intra-cellularis meningitidis.

2. *Meningitis from the Lymph-Vessels.*—These cases are mostly infections by streptococci in connection with peripheric suppuration about the skull; caries of the temporal bone, of the ethmoid, bone tuberculosis, bone syphilis, traumatic osteitis of the skull.

Huguenin says the subdural space is a protection; but a direct bridge through this space is formed by the pia-sheaths of the nerves of exit, the pia-sheaths of the vessels passing downward, especially of the jugular and carotis and the Pacchionian bodies. The pia may be affected only directly. Suppurations which reach the brain in other ways are confined to the dura.

3. *Meningitis from the Veins.*—The cause is here mostly a sinus thrombosis from penetration of the pia by micro-organisms through the Pacchionian granulations, as from caries of bones and diseases of the external skin, and of the subcutaneous connective tissue, erysipelas, furunculosis, and the like. It is not yet definitely settled that syphilis and tuberculosis of the bone may excite a meningitis through the veins, but the virus of an erysipelatous meningitis certainly finds its way through the orbits and the sinus cavernosus.

4. *Meningitis from Brain Tumor.*—Rare cases may thus arise from a central necrotic tumor undergoing softening.

5. *Meningitis from the Spinal Column.*—Huguenin reports a case of streptococcus meningitis from a gangrenous bed-sore, which had broken inward in the course of transverse myelitis. Cases of gonorrhœal meningitis have been reported by Hayem and Parmentier. Gull reported two autopsies, one showing softening of the cord, the other meningitis.

Adénot distinguishes three varieties of parasitic meningitis as produced respectively by micrococci, bacilli, and mixed forms. The first may be divided into the forms produced by the micrococci of pneumonia, or the micrococci of Weichselbaum, and the streptococcus. By the term pneumococcus is understood the diplococcus of Fraenkel. What *rôle* the pneumococcus of Friedländer plays in meningitis is questionable. Concerning the bacillar meningitis, forms have been described by Neumann, Schäfer, Adénot, and others, resembling the typhoid bacillus of Eberth, but not identical with it. Concerning the mixed forms, Monti produced meningitis in one case by injecting the coccus of Fraenkel into the dura, and afterward the streptococcus into the blood. The cause of epidemic cerebro-spinal meningitis cannot be satisfactorily fixed as yet.

Boulay and Courtois-Suffit report the case of an habitual drinker, aged forty-four, who died after three days' illness, and upon post-mortem there were found suppurative meningitis and peritonitis, while the other organs showed no change. The authors found in the suppurative exudations capsule cocci, and besides these, in the exudation of the peritoneum, other bacteria. A mouse inoculated with the pus of the brain membranes died in twenty-four hours. The spleen was markedly swollen, and "characteristic pneumococci" were found in the blood. There was, therefore, in this case, a remarkable extra-pulmonary localization of the pneumococcus, produced perhaps by the chronic alcoholism. The exudation was green, thick, and plastic, characteristics which enabled the author to predict the presence of the diplococcus pneumoniæ.

In the ensuing discussion, Sevestre declared that he had encountered a case of peritonitis in a young girl recently where the exudation was accumulated in the left iliac fossa. In pus removed by puncture Netter demonstrated the pneumococcus. Netter also reported a case of meningitis and peritonitis in a small child where he found pneumococci in the blood, and supported the declaration of Debove that he was able to declare the existence of the diplococcus pneumoniæ in extra-pulmonary localizations from the macroscopic condition of the exudation, a declaration which had been advocated in former statements by Netter. But the diagnosis must not rest upon these conditions. It may be determined only by bacteriological examination.

Gabbi and Puritz declare that the occurrence of a meningitis or endocarditis, either or both, in the course of a croupous pneumonia, or during the period of convalescence, is, if not a frequent, at least an established sequence, and either may properly be regarded as a complication of this disease.

Weichselbaum, as early as 1884, declared that the micro-organisms of croupous pneumonia might be the cause of meningitis, and Foà and Bordoni-Uffreduzzi produced meningitis by the inoculation of animals with the pneumonic diplococcus. The same results were obtained by Fraenkel and later by Netter.

Lancereaux and Besançon were able to demonstrate Fraenkel's capsule microbe in many cases of endocarditis.

A review of the later works of Weichselbaum, Vinet, and others, shows with certainty that the above-mentioned micro-organisms may produce an acute inflammation of the meninges or of the endocardium.

Foà finds an organism that partakes partly of the character of the meningococcus and partly of that of the pneumococcus. If the latter is cultivated anaërobically it takes on the properties of the meningococcus in twenty-four hours. The meningococcus can be temporarily transformed into the pneumococcus, if it is inoculated at the same time with the staphylococcus pyogenes aureus.

Klippel reports a case of infection by micro-organisms in the course of mental disease. The patient, a fifty-year-old gardener, had suffered for ten years with dementia and slight paresis of the left side of the body. He was seized with sudden fever, extensive muscular rigidity and convulsions, and died comatose in three days. The most careful investigation failed to disclose any laceration or break of the surface, which could have furnished an avenue for outside infection. The post-mortem revealed an extensive purulent meningitis, extending from

a centre of softening, which had been regarded as the cause of the dementia. Microscopic examination of the pus showed the pneumococcus. Such secondary infections in the course of insanity occur frequently. Klippel claims that the pathogenic micro-organisms circulating in the blood find in the diseased centre a locus minoris resistentiæ.

The differential *diagnosis* between simple and tubercular meningitis may be established by the use of tuberculin, though the procedure is not wholly without danger in the tuberculous form.

In pseudo-meningitis (Boulay), aside from partial paralysis, all the symptoms of meningitis may be present, and the case may look very doubtful until unmistakable hysterical symptoms develop; or recovery occurs suddenly, sometimes after a convulsion.

Treatment.—Dauchez in the case of a child, aged four, was able to relieve excruciating headache at night only by narcotic doses of morphine and chloral, but succeeded during the day with antipyrin, in small doses—.02, .04, every hour for four doses. The distressing outcry ceased, though the child gave vent to sighs from time to time.

Essex-Wynter was able to give some relief in four cases of tubercular meningitis by puncture of the vertebral canal, and discharge of cerebro-spinal fluid. The breathing improved; sometimes coma was relieved. Irresponsive pupils regained the reflex, but all improvement was only temporary.

Opium remains the anchor in the treatment of meningitis. Dennison cured a chronic case with tuberculin.

Pachymeningitis, External and Internal.—As illustrative of the rarity of the disease, Northrup declares that he encountered internal hæmorrhagic pachymeningitis only four times in one thousand five hundred autopsies. In three cases, severe and prolonged convulsions finally terminated in death. In the fourth case there was no symptom except restlessness and slight rigidity. The patient died of acute enteritis. There was no paralysis in any case.

Bailey reported a case in a man, aged seventy-two, a subject of senile melancholia; death from convulsions. Autopsy disclosed encapsulated hæmatoma under the dura of the right parietal bone. The hæmatoma was composed of coagula of different ages, and there was a recent rupture in the arachnoid cavity.

Ruhemann found in percussing the skull in a great number of patients, that sensitive surfaces could be detected only in chronic pachymeningitis, and then with great regularity. In genuine epilepsy the remarkable observation was made that in twenty of twenty-nine cases a circumscribed portion of the temporal bone was sensitive.

Adamkiewicz emphasizes the fact that in spinal pachymeningitis it is the extension of the inflammation rather than the pressure of the connective tissue which damages the nerves and cord.

Hoffmann remarks that, notwithstanding the fact that the intra-cranial diseases as sequels of affections of the ear have long since received full consideration, purulent pachymeningitis externa, the most frequent form of intra-cranial inflammation in consequence of ear disease, still receives very little study. Most of the text-books do not even consider an isolated inflammation of the dura. Hoffmann collected from literature one hundred and two cases in which the autopsy, with certainty, confirmed participation of the dura. From his own and other studies, the author recognizes (1), a form in which pus occurs as a deposit on the outside of the dura, and (2), a form in which it shows itself as an extra-dural abscess.

The following are the conclusions: Purulent external pachymeningitis is the most frequent of the intra-cranial diseases after inflammations in the middle ear, but on account of its uncertain symptomatology it is recognized in life in only a few cases.

It is the most frequent cause of fatal intra-cranial diseases—meningitis, sinus phlebitis, and brain abscess. These consequences are favored by the long duration of pachymeningitis and retention of its pus.

So soon as the bones become diseased in consequence of affection of the middle ear, suspicion should be excited of a complication with pachymeningitis.

Treatment must be operative. It consists in trephining the mastoid process and exposure of the inflamed dura. *James T. Whittaker.*

MENTHOL. The decided antiseptic qualities, and the safety with which it may be administered, have led to the internal use of menthol in a number of diseases and conditions in which an antiseptic is indicated. In pulmonary and laryngeal phthisis it has been recommended to combine its internal use with inhalations and local application to the diseased parts when within reach. It is thought to give rise to a general amelioration of the symptoms, promoting expectoration and reducing the amount of the sputa, and lessening the night-sweats and fever. It does not irritate the stomach or kidneys, does not cause hæmoptysis, or produce any bad effects. For internal use from fifteen to twenty grains are given two or three times, and increased to five or six times, a day. It has also been used in the form of hypodermic injections, when mixed with vaseline in the proportion of ten parts to one hundred. For laryngeal phthisis it is advised to begin with a ten per cent. solution and gradually increase the strength until a fifty per cent. solution can be applied; if too strong a solution be used at first it produces irritation of the parts. Its use is followed by a relief from pain and a reduction of the local inflammation and infiltration; a healing of the superficial ulceration follows, but it does not seem able to heal the deeper ulcers. The intra-tracheal use of menthol has been adopted by Dr. Brookhouse (*British Medical Assoc.*, 1892)—one drachm of a twelve per cent. solution in pure olive oil is introduced into the trachea twice daily. This must be effected with the aid of the laryngoscope and syringe, the curved tube of the latter being introduced about half an inch below the rima glottidis. This method does not cause any pain or distress if carefully applied. The inhalation of the drug may be easily obtained by placing the menthol in a bottle with two glass tubes. As it volatilizes at 113° F., by placing the bottle in a dish of hot water, a copious supply of fumes is produced. The patient may take five or six inspirations several times a day, beginning slowly, as too great quantities might provoke irritation and choking. Menthol has also been employed in asthma and chronic bronchitis and laryngitis. In diphtheria it is advised as a local application in the form of a powder, one part being well mixed with ten or twenty of sugar. The powder is applied with a camel-hair brush, the membrane being removed as fully as possible. The application should be repeated twice or three times a day. It acts as a constant disinfectant, destroying the specific poison, and on the second or third day the membrane disappears, leaving a clean and easily healing ulcer.

Menthol has been found to have an anti-emetic action, and has proved of great service in all forms of vomiting, particularly when pregnancy is the cause of this distressing symptom. This effect is supposed to arise from a purely local stimulant action of the drug. For this purpose it is best administered at the commencement of nausea, before the vomiting occurs; a suitable way of giving it in this trouble is to prepare a solution in oil of twenty per cent. and place ten drops on sugar, and form it into a mass which is readily taken and swallowed by the aid of a mouthful of water. Another preparation is to mix menthol, one part; spirits of wine, twenty parts; simple syrup, thirty parts. One teaspoonful every hour until nausea is relieved.

The following combination also forms a permanent mixture: Menthol, two drachms; alcohol, one ounce; glyceriue, one ounce; syrup, one ounce. It may also be given in the form of pills: Menthol, one drachm; powdered acacia and sugar, of each half a drachm; to be made into forty pills.

Menthol continues to be of service as a local application in neuralgia, sciatica, pruritus, and other painful affections, and in various parasitic diseases. Its local use has been facilitated since it was discovered that when mixed

with certain other analgesics it assumes a fluid form. When triturated in the following proportions, colorless, transparent oily fluids are produced, which may be used for the purpose of inhaling or as local anæsthetics: Menthol in equal parts with thymol, absolute phenol or chloral; menthol three parts, camphor two parts; menthol two parts, butyl-chloral-hydrate one part; and menthol two parts, with one each of carbolic acid and butyl-chloral-hydrate. *Beaumont Small.*

MERCURY (Hydrargyrum, U. S. Ph.). INTRODUCTION.—In taking up the study of mercury after a lapse of six or seven years it must be borne in mind that material changes have taken place within that period, although it is doubtful if salts and preparations of the metal are any more highly prized by physicians and surgeons now than at any time during the past decade. That mercurials possess a wide range of application cannot be denied, but after a careful and comprehensive survey of the kaleidoscopic changes that have occurred in the minds of intelligent practitioners within a quarter of a century, there is no doubt but that their medicinal properties have been greatly overrated, and at the same time the deleterious action upon the economy largely underestimated. Judging by the character of reports appearing from time to time in current medical literature, it is evident that mercurials are now employed with a nicer discrimination, with more intelligence looking to the definite effects which are likely to follow, and more with a view to their conservative influences than ever before. However, this happy condition of affairs has not been reached through careful and deliberate investigation of the clinical properties of the drug, but, on the contrary, by a series of most reckless and flagrant abuses—a sad commentary when considered in connection with the coincident advancement in other sciences.

Through a strange concatenation of circumstances in teaching and practice—due largely to the fact that mercury was supposed to possess a so-called *alterative* effect upon the organism—physicians appeared to have lost sight of the oft-repeated caution that it was a substance foreign to the human economy, and an acrid, irritant poison. Its properties have been, in many instances, estimated from the clinical point of view, by considering the temporary or immediate benefits from its use rather than from the scientific standpoint, which would bring into prominence the ultimate disorders following its injudicious or long-continued employment. In studying these properties, therefore, in the light afforded by modern investigation, it will be necessary to take into account these facts, viz.: That mercury is a substance foreign to the organism, and an irritant poison producing both immediate and remote changes in structure, whether used internally, locally, or hypodermatically. And in view of the additional fact that the so-called "alterative" action has come to be regarded as without scientific meaning, and lacking in definiteness, the present seems an opportune moment for advancing certain evidences that promise to offer an explanation of its action, an explanation that shall be more in keeping with the demands of modern science, while at the same time strictly within the range of practical medicine. Scientific facts, supported by clinical facts, will go very far with intelligent practitioners in elucidating the mysteries which have so long surrounded and obscured the therapeutics of this important remedial agent.

In order to accomplish this laudable purpose it will be necessary to consider the nature of its cumulative action, and the causes at work which, apparently, prevent or modify this action in children. It will also be desirable in this connection to study immediate and remote effects, the primary and secondary actions of both soluble and insoluble salts and preparations, all of which can best be accomplished by a critical examination of its pharmacology, which naturally includes its toxicology, physiological actions in medicinal doses, and mode of elimination. This study should include, in short, a complete analysis of its general and specific influence upon metabolism, meaning by that its constitutional as well as specific action upon different organs and tissues, including in this category the entire nervous system. And, finally, having thoroughly digested and sifted all available information upon these various topics, the concluding section will be devoted to its therapeutic applications, the different diseases being grouped to facilitate study and reconcile the conflicting views hitherto held.

As a preliminary to the present paper, it will be profitable to consider briefly some of the more recent mercurial preparations, and to pass in review the antagonists and incompatibles. In the original article by Professor Curtis (REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, Vol. IV., 1887, p. 737), the Pharmacopœial preparations were so fully studied that it does not appear necessary at this time to attempt a remodelling of that section, although their properties will be referred to incidentally in connection with toxicology. For more detailed information covering the toxicology the reader is referred to the contribution of Professor Hills (loc. cit., p. 744), which is exceptionally full and complete.

MERCURY COMPOUNDS.—The following list includes the principal mercurial compounds * aside from the Pharmacopœial products which have recently been brought to the attention of the profession. While some of them undoubtedly possess distinct therapeutic properties, the greater number are lacking sufficient clinical investigation to warrant their general use.

Mercuric Benzoate, $(C_6H_5COO)_2Hg,H_2O$, occurs in the form of small colorless crystals, tasteless and free from odor; readily soluble in alcohol and hot water, but sparingly soluble in cold water. This preparation has been used hypodermatically suspended in liquid paraffin (Stukowenko) for the treatment of syphilis, and also in combination with sodium chloride in watery solution (Cochery) for the same disease. *Dose*, one syringeful daily of a solution containing the following proportions of the different ingredients—3 to 1 to 400.

Mercuric Carbolate or Phenylate, $(C_6H_5O)_2Hg$, occurs in the form of colorless needles, soluble in hot alcohol (1 to 20), ether, or a mixture of alcohol and ether, and in glacial acetic acid; insoluble in cold water or cold alcohol. Mercuric carbolate has been employed to a limited extent (Schadeck) in the treatment of syphilis. *Dose*, for an adult, gr. $\frac{1}{8}$ to $\frac{1}{4}$, two or three times a day, and for children in proportion.

Mercuric Formidate occurs as a solution, produced by the action of formamide upon mercuric oxide. It has the advantage of not coagulating albumin, is rapidly absorbed, excretion taking place through the kidneys.

Mercuric Imido-succinate, $[C_2H_4(CO)_2N]_2Hg$, occurs in the form of a white, lustrous, crystalline powder; soluble in twenty-five parts of water or three hundred parts of alcohol. The substance was first described in 1852 (Dessaignes), and in 1888 was recommended as an antisyphilitic (von Mering, Vollert). *Dose*, subcutaneously, gr. $\frac{1}{6}$ in watery solution, with or without the addition of cocaine.

Mercury l'Alananate is a white, crystalline powder derived from lactic acid and propileglycole; soluble in three parts of cold water. It is prepared by dissolving the alananine in five times its weight of distilled water, and while boiling, small quantities of mercury hinoxide are added so long as it dissolves. *Dose*, subcutaneously (de Luca) gr. $\frac{1}{12}$ to gr. $\frac{1}{4}$ daily. It is said this treatment in syphilitic cases, continued for a period of forty-five days, has frequently proved sufficient.

Mercury Naphthalate occurs in the form of a lemon-yellow, odorless powder, containing 30.8 per cent. of mercury, insoluble in water. It was first employed in the treatment of syphilis (Jaddasohn, Zeissing), but proved unsuitable owing to the violent pain produced. *Dose*, internally, one grain.

Mercury Oleate, $Hg(C_{18}H_{33}O_2)_2$, a true chemical product containing 28.3 per cent. of mercuric oxide; it is in the form of a brownish-yellow or yellowish-gray unc-

* The author desires to acknowledge his indebtedness for much of the information on this topic to Helbing's Modern Materia Medica, 3d edition, 1892.

tuous substance, having the odor of oleic acid; soluble in benzene, but not in alcohol, and at ordinary temperatures is of the consistency of an ointment. It is best prepared by the double decomposition of sodium oleate (Castile soap) and mercuric nitrate, but the process is somewhat complicated.

Oleate of mercury as now prepared is a stable product, and has been favorably received as an acceptable *substitute for mercurial ointments*, being a more cleanly application, does not become rancid, and, besides, is more rapidly absorbed. It is generally employed as an external application in the strength of five to ten per cent. Constitutional effects may be produced to a limited extent by the use of mercury oleate, and it may therefore be substituted for internal medication when the condition of the stomach forbids the internal use of the mercurials, but its principal field has hitherto been confined to the treatment of diseases of the skin, specific and non-specific, including also parasitic affections. It appears to be especially adapted to diseases of the skin which are characterized by an indolent condition of the structures, eczema, tumors, pigmentation, and all forms of induration or thickening; it should not be applied to ulcerations where there is a solution of continuity.

Mercuric Oxycyanide, $Hg_2O(CN)_2$, has been employed to a limited extent (Boer) as an antiseptic, and is said to be superior to the sublimate in this respect, being less caustic, free from any coagulating action upon albumin, and less harmful to instruments. The following points are advanced in its favor: 1, Precipitates albumin only slightly; 2, less irritant than sublimate solutions; 3, not so readily absorbed; 4, antiseptic power in keeping soup six times stronger than sublimate; 5, more efficient as an antiseptic and safer in treating suppurating and mucous surfaces, owing to tolerance and feeble absorption.

Mercuric Peptone occurs in the form of a yellowish liquid, having a saline, feebly metallic taste, and slightly acid reaction. It was originally introduced for hypodermatic use, and is said to be mild and efficient, causing no pain or abscesses. *Dose*, one c.c., said to be the equivalent of gr. $\frac{1}{6}$ of the bichloride. (See Glutine-peptone Sublimate.)

Glutine-peptone Sublimate occurs in the form of a white, lustrous, hygroscopic powder (prepared and on sale in the form of a one per cent. solution) containing twenty-five per cent. of mercuric chloride. It is prepared by the action of hydrochloric acid on gelatin—a double compound of glutine-peptone hydrochloride—with sublimate. *Dose*, subcutaneously, one Pravaz syringeful (Hüfler), the equivalent of gr. $\frac{1}{6}$ mercuric chloride.

Mercuric Salicylate, $C_6H_4OCO_2Hg$, is in the form of a fine, white powder, tasteless and odorless, and acid in reaction. It was employed as early as 1887 (Silva-Aranjo), and again more recently (Schadeck), as an internal and external remedy in syphilis, and is said to be mild, yet energetic. It has also been employed by intramuscular injection suspended in mucilage, and locally in the treatment of gonorrhœa in weak solution as an injection. *Dose*, gr. $\frac{1}{10}$ to $\frac{1}{4}$, in pill form.

Mercury Sozoiodol, $[C_6H_2I_2(I_2)(OH)SO_3]_2Hg$, is in the form of a lemon-yellow powder; moderately soluble in sodium chloride solution, but scarcely soluble in water (1 to 500). In strong solution this product is an irritant to the tissues, but its insolubility recommends it for hypodermatic use in the treatment of syphilis. According to Schwimmer it is superior to all sozoiodol preparations in its curative value and certainty of effects. *Dose*, one grain, deposited in the gluteal region.

Mercury Stearate, recently brought to the attention of the profession, is in the form of a white, unctuous powder, and is said to contain twenty per cent. of mercuric oxide—about the same as blue ointment. It differs from the oleate in being entirely free from oleic acid, and may be used for insufflation, or as a "dry ointment" in place of the usual greasy applications when the local action of mercury is desired.

Mercury Tannate occurs in the form of brownish-green scales, tasteless and odorless; insoluble in water and alcohol, although when brought into contact with either tannin is given off. The theory of its action (Lustgarten) is based upon the assumption that metallic mercury is set free when exposed to the alkaline contents of the small intestine. *Dose*, one to two grains, an hour after eating.

Mercuric Thymolate, $(C_{10}H_{13}O)Hg\text{-}HgNO_3$, in the fresh state, is in the form of a colorless powder, tasteless and odorless; after exposure it gives off a faint odor of thymol, with change of color to a reddish hue.

Mercuric Thymolacetate, $(ClOHI_3O)Hg\text{-}HgC_2H_3O_2$, is a substance similar to the foregoing, although the latter is that principally employed in syphilis (Kobert). It has been especially advocated also in the treatment of pulmonary tuberculosis (Trangen), both in the early stage and in those cases far advanced in the disease, the medicament being suspended in liquid paraffin. For syphilis it is given internally or hypodermatically in the manner stated. *Dose*, internally or subcutaneously, gr. $\frac{1}{12}$ to $\frac{1}{6}$.

Mercury-zinc Cyanide, $[Zn_4Hg(CN)_{10}]$, occurs in the form of a white powder, which is said to consist of mercuric cyanide (not to exceed thirty-six per cent.) whose particles are "occluded" from the action of water by the insoluble zinc cyanide (Dunstan); insoluble in water. Mercury-zinc cyanide is obtained by adding a soluble zinc salt to a solution of the cyanide of mercury and of potash. The substance was originally introduced by Sir Joseph Lister as an antiseptic and non-irritant dressing, and is now employed by a limited number of surgeons with most gratifying success. The strength of the solutions used for the field of operation is 1 to 2,000, and that for compresses is 1 to 500.

Triturations of Mercury and its Salts have, within the past few years, come into very general use for internal administration, and their employment has been attended with such uniformly satisfactory results that it is but a question of time when this practice will be adopted in nearly all ordinary cases. The causes which have been instrumental in bringing about this change will be discussed under the head of Antagonists and Incompatibles, *q. v.*

Antagonists and Incompatibles.—When a lethal dose of corrosive sublimate has been taken into the stomach, albumin in some form—white of egg—should be administered and emesis secured as promptly as possible, before the resulting albuminate of mercury is redissolved by excess of albumen. Demulcent drinks are usually advocated, in the belief that they will protect the mucous membrane of the stomach from the irritant action of the poison; but mucilaginous substances do more than this, inasmuch as they cling to, and hold in suspension, such foreign substances as mercury albuminate, the form in which mercury enters the circulation. Mercurial salts being proverbially uncertain in some respects—especially the bichloride—they should be given preferably in the form of triturations, although this does not necessarily apply to the insoluble salts like the biniodide when suspended in mixtures. But even the use of this salt, as in the "mixed treatment," is far more satisfactory in the form of triturations, since incompatibles are avoided, smaller dosage required, and the untoward effects, immediate and remote, reduced to a minimum. The facility with which therapeutic effects may be secured by the exhibition of small doses of blue pill and calomel, prepared in this form, practically excludes the question of incompatibility. Both the soluble and insoluble preparations in this form, alone or combined with other suitable medicants synergistic in character, may be exhibited in suitable doses under proper dietetic regulations without regard to the possible dangers arising from their administration in bulk.

A note should be made to the effect that starchy foods delay or cause irregular absorption, while a nitrogenous diet with free ingestion of liquids heightens the activity of mercurials. Constipation, by interfering with elimination, may produce salivation, and under such conditions a dry diet, by lessening the urinary water, is not infrequently the exciting cause of occult renal disorders. Exposure to cold is also inimical to the therapeutic action of mercurials, while diaphoretics tend to promote con-

stitutional effects—favorable when the dose is small, but unfavorable when toxic symptoms are imminent. Looseness of the bowels following the exhibition of mercury may be counteracted by the temporary administration of opium or some of its preparations (codeine sulphate), although it is better to avoid distinct physiological manifestations by diminishing the dose, regulating the diet, and improving the hygienic environment.

So-called idiosyncrasy, when mercurials are used in appropriate dosage, is generally and principally a merely accidental or coincident effect, due to physical (personal) conditions, habits as to diet, exposure, hygiene, and the like, since there is reason to believe that the condition of the physical system exercises a more decided influence in favoring this manifestation than does the nervous system. Indeed, it appears as if the effects upon the latter were indirect or secondary, although there doubtless are reflex effects resulting from molecular changes which are not altogether independent of the nervous system. The effect of mercury upon the system may be compared to the effect of adding coal to a furnace when combustion is actively going on; the added fuel may cause a temporary lull in the heat dissipation, but this is followed by increased combustion and augmented heat. In the case of the furnace it is the coal which is destroyed, while in the case of the human organism it is the tissues that are consumed, each dose of mercury beyond that requisite being attended with increased tissue-metamorphosis.

Pharmacology.—In studying the *Toxicology* of mercurials as a whole or specifically it is not necessary or advisable to recapitulate from text-books, nor sift from current literature the details concerning their peculiar actions in causing death or contributing toward the production of pathological changes in the organism. It will be sufficient for our purpose to pass in review the various Pharmacopœial products, with the addition of some brief notes relative to their special properties and activities.

The preparations of mercury proper include mercury with chalk, blue mass, blue ointment, mercurial plaster, and mercurial plaster with ammoniacum. None of these preparations possesses any marked poisonous properties, and they may be used with benefit in properly selected cases, provided the dose be small and the drug not too long continued. *Moderate dosage*, for therapeutic effects, may be stated as follows: Mercury, with chalk and blue pill, grain $\frac{1}{10}$ at hourly intervals until six to twelve doses are taken, or two to four doses of one grain at longer intervals. *Synergists*, such as podophyllin resin, aloin, ipecac, ox-gall, salines, etc., will heighten the effect of small doses and lessen the dangers of toxic symptoms. Liberal draughts of hot water may also be of service in promoting diffusion and elimination, and there may be a demand for the exhibition of minimum doses of opium, pilocarpine, atropine, strychnine, etc., to meet special indications, and, as a rule, adjuvants are most serviceable when given separately, although administered at the same time.

Preparations of the chlorides include corrosive sublimate (bichloride), calomel (sub-chloride), ammoniated mercury (not used internally), and ointment of ammoniated mercury.

Of the two preparations belonging to this class which are used internally the bichloride is by far the most actively toxic, frequent reports having appeared showing unmistakably that it produces both immediate and remote pathological changes sufficiently characteristic of its poisonous action to be recognized both macroscopically and microscopically. Calomel, on the contrary, owing to its insolubility, is comparatively mild as a poison, so far as its immediate effects can be observed, although its remote action, when long continued or frequently repeated in substantial dosage, is antagonistic to a healthy state of nutrition, as will be shown presently.

The dose of these two preparations, as usually recommended, is entirely too large—if we desire to avoid the bad effects. Both are popular remedies in the treatment of diseases of children, who seem to be less susceptible than adults to the toxic action of the drug; and there are grounds for suspicion that the practice referred to is an important factor in prolonging convalescence, if not a fruitful source of factitious disease. In ordinary acute cases, where indicated, grain $\frac{1}{1000}$ of corrosive sublimate, or grain $\frac{1}{20}$ of calomel, given at hourly intervals, will fulfil every therapeutic indication, while the dangers incident to the use of large or toxic doses are avoided. The advice given in the preceding section concerning synergists and adjuvants applies with equal force to the administration of the chlorides. The antiseptic applications of corrosive sublimate will be considered under the head of Surgical Practice, *q. v.*

Preparations of the oxide include yellow oxide (*oxidum flavum*), used principally in the preparation of yellow ointment and mercury oleate, red oxide, and ointment of the same. The preparations belonging to this class are decidedly irritating, and are seldom used internally. The oleate (*q. v.*) is the only one which has attained any considerable degree of popularity.

Preparations of the iodide include the red iodide (biniodide), Donovan's solution (solution of iodide of arsenic and mercury), and the green iodide (protoiodide). Both the biniodide and green iodide have shown distinct therapeutic properties in the treatment of subacute and chronic diseases, specific and non-specific, their virtues being due largely to their practical insolubility and the fact that doses sufficient to produce physiological or toxic effects are extremely irritating to the gastro-intestinal tract. The incorporation of iodine with the mercury likewise exercises an important function, since the remedies, being but slowly diffused throughout the different structures, produce a more or less constant action upon the protoplasmic cells, by which metabolic changes are stimulated.

The usual dose of the biniodide, prepared by thorough trituration, for adults in the case of gastro-intestinal, hepatic, and syphilitic affections, need not exceed grain $\frac{1}{100}$ three or four times a day. The dose of the protoiodide should be about double this amount, grain $\frac{1}{50}$. In the treatment of *acute diseases of children*, peculiar to the summer season, with evidences of hepatic involvement, vomiting, diarrhœa, dysentery, pain, tenesmus, etc., the biniodide, in doses of grain $\frac{1}{1000}$ hourly, is a superior remedy. It is quite as prompt in its action as the bichloride, and the benefits appear to be of a more permanent character, probably because of its insolubility as previously stated. It is also of service in the treatment of *all throat affections*, owing to its local antiseptic properties and its antiseptic and stimulating action upon the stomach and liver respectively.

Of the acid combinations it is only necessary to say that they are actively poisonous. The nitrate is employed as a caustic and in the preparation of citrine ointment, the subsulphate (yellow) as an emetic. Mercuric sulphide is employed for fumigation, now rarely used, and the cyanide is actively poisonous. The latter in combination with zinc has recently come into use as an efficient antiseptic.

The foregoing summary is put in evidence to show that mercurials, in whatever form presented, are all either *immediate or remote poisons* to the organism, although this declaration must have slight effect since all practitioners readily admit the fact. It becomes necessary, however, to reconcile its therapeutic value, long established, with its well-known properties as *a protoplasmic poison*, inimical to all animal and vegetable life. And this brings us to the consideration of questions that have long vexed the minds of physiologists and clinicians alike, questions of weighty significance, pregnant with important but unsolved truths that have swayed the practice of the healing art generation after generation from the dawn of history down to the present time.

Turning to the text-books of the day we find mercury classed as a tonic, purgative, alterative, antiphlogistic, antiseptic, and sorbefacient, and, to a limited extent, cholagogue; but to the scientific mind this information conveys nothing definite, exact, or positive, as it has never been demonstrated either definitely, exactly, or positively how these manifestations were brought about. Of course we know that a peculiar fetor of the breath and

metallic taste in the mouth are early indications that "the drug is affecting the system," but evidently this is a loose way of calculating. It must be apparent that these early indications are, in fact, secondary or remote effects, and that the immediate or direct effects have been overlooked. For example, we know that corrosive sublimate taken in lethal dose causes vomiting, purging, and tenesmus, perhaps suppression of urine, and that its effects are especially marked upon the lower bowel, manifested at times by bloody stools, but apparently there is a long distance between this morbid complexus and salivation. Twenty, forty, or sixty grains of calomel will produce decided reflex nervous symptoms, but, on the other hand, medicinal doses, long continued, are almost certain to be followed by stomatitis. That stomatitis is a secondary effect is shown by the associated elevation of temperature.

Experimental workers speak of the *physiological action and effect*, and clinicians talk about *therapeutic action and effect*, just as though the two words, action and effect, were interchangeable or mutually convertible terms, when in fact there is a wide difference between them. What intelligent medical practitioners want to know is: *How do mercurials act* in order to produce the effects observed? The latter—the effects—the merest tyro in therapeutics can comprehend, but it remains to give a satisfactory working explanation of the *modus operandi* by which these effects are produced. In short, is there any other possible translation of the metamorphoses produced by mercurials than that they possess "*alterative*" properties?

In attempting to reply to these questions let us start by accepting as true the belief that the conservative processes of Nature tend toward the elimination of poisons and foreign substances. Now we know that certain channels are available for this purpose, viz., the liver, salivary glands, alimentary tract, skin, kidneys, and the pulmonary and bronchial mucous membrane. Mercury entering the blood-vascular system, either as an albuminate or oxy-albuminate, is not carried direct to the organs or structures named, but indirectly through the lymph-vascular system. It is therefore brought into contact with the protoplasmic cells, upon whose integrity the vitality of the various organs and tissues depends, elimination being finally effected from the intercellular fluid through the epithelial cells. If we proceed, now, to consider *the normal condition and functions of protoplasm*, recalling the well-known facts relative to its capacity for taking up and storing oxygen for its own proper work, its ability to produce ozone and thus stimulate katabolic processes, it will be apparent that when an organic substance foreign to the economy—a poison—is brought into contact with it, functional activity will be increased. Heightened functional activity usually means in such cases an increased discharge of carbonic acid and katabolic products, together with renewed activity in the up-building process. This is substantially what has long been recognized as cellular activity, and working principally in the direction of retrograde metamorphoses, studying degenerative effects, it formed the basis of Virchow's celebrated treatise, "Cellular Pathology." When we turn our attention in the direction of reconstructive metamorphosis with the object of learning the peculiar influences at work in connection with the exhibition of remedial agents, our line of investigation is practically in the opposite direction. In other words, our studies lie in the direction of *cellular therapy* rather than toward cellular pathology. But the two currents of thought are so intimately blended and mutually interdependent—like the warp and woof—that it is almost impossible to make satisfactory progress unless we take both into account in our reckoning. Simply to know or understand what is covered by the term "alterative," however, is not sufficient; we must have some definite, exact, and positive knowledge concerning the difficulties to be met and overcome in treating disease, and therefore, as a preliminary to the practical adaptation of cellular therapy, the student must be well-grounded in the principles underlying normal physiology and cellular pathology.

And there are good and sufficient reasons for insisting upon this course, since the ultimate object of medical study is to restore impaired or suspended function, which can only be successfully accomplished by the re-establishment of cellular activity. Thus the therapy best adapted to restore the functions of disordered cells is that which will prove most successful in removing disease and its symptoms; but care must be exercised in the exhibition of remedies in order to avoid what might be called "*cumulative*" effects, or the depression consequent upon over-stimulation. For instance, the early indications that mercurials are affecting the system are, in fact, evidences of toxic activity, evidence that there has been sufficient "action" upon the protoplasmic cells, their nutritive pabulum contained in the intercellular fluid, or their nerve-supply, to produce the effects observed, namely, fetor of the breath and metallic taste in the mouth. The proof is therefore conclusive that, while mercurials are protoplasmic poisons, it is to this property that they owe their therapeutic virtues as tonics, purgatives, alteratives, antiphlogistics, antiseptics, sorbefacients, and, as will be shown presently, their value as cholagogues, and the term cellular therapy, therefore, appears to be well chosen.

In the case of mercurials, for example, *the therapeutic effect is a resultant*, the two forces being the disease and the medicine, the conservative processes of cell-life being temporarily impaired or suspended. The depressing tendencies produced by disease, ptomaïnes, leucomaïnes, etc., are counteracted or overcome by the irritating, or, as it is usually called, stimulant action of the minute quantity of poison to which the protoplasmic cells are exposed. These *effete products are discharged or burnt up by the oxygen or ozone of the protoplasmic cells*, so that these latter are *changed or "altered"* in such manner that better prepares them for the performance of their normal functions, and to this circumstance may be due the word "alterative." Clothed in this new dress the term has a greater significance to the clinician, because it rests upon a foundation that is both scientific and practical.

The usual study of *physiological actions* includes also the *effect upon the blood.* According to the experimental studies of Harley, mercuric chloride added to blood lessens the evolution of carbonic acid, and, at the same time, increases the absorption of oxygen, evidence that it stimulates oxidation; but, on the other hand, albuminate of mercury added to blood in like manner gradually destroys the red blood-corpuscles, facts pointing to the necessity for exercising the greatest care in its administration. In comparing these results with the clinical evidence advanced by Keyes (*American Journal of the Medical Sciences*, January, 1876), showing that small doses of mercury (gr. ¼ of the protoiodide t.i.d.) increase the number of red corpuscles in the absence of disease, it is easy to understand the causes which combine to produce the apparently conflicting results. In truth, they do not conflict at all, but merely express scientific facts entirely independent of each other.

An observation should be made here to the effect that the therapeutic results following the exhibition of mercury are not all direct, since the increased oxidation which it causes in the system means more active metabolism, augmentation of the red blood-corpuscles, and improved primary assimilation. These are what might be termed *consequential benefits;* and in the light of these facts, and our knowledge that the inorganic substance is eliminated from the organism unchanged, it is not deemed necessary to combat the assumption that mercury must, in some occult manner, become an integral part either of the blood or tissues in order to effect reconstructive metamorphosis.

Upon *the muscular system* mercury produces a somewhat anomalous effect. For example, we might suppose that increased oxidation would be attended by augmented capacity for work; but such is not the case, although mercury has no material influence upon muscular irritability. And this explains in a measure why patients who have taken medicinal doses of the drug for a considerable time finally begin to show evidences of cardiac weakness and require tonics. The respiratory muscles

likewise show impairment of their capacity for work, so that in calculating the gains from stimulation of the internal respiratory function, we must not overlook the fact that increased dosage or continued administration may produce symptoms which are but transitory, evanescent, or misleading.

In addition to its action as a protoplasmic poison at the points of elimination by the *renal structures*, large doses have the effect of producing chronic interstitial nephritis by calcareous deposits in Henle's loops, which block up the tubules, and this in turn is followed by subacute inflammation of the glomeruli and tubules with atrophy and cirrhosis (Brunton), being similar to the effects produced by both lead and potassium chlorate.

That mercury profoundly affects the *nervous system* is confirmed by the remarkable manner in which persons in health are affected when exposed to its vapors. The irritability, melancholia, and in some instances furious mania, with other evidences of mercurialization that have been observed, afford abundant proof that either directly or indirectly it effects extraordinary changes in the centres of organic life that seriously interfere with the normal functions. In the case of leeches, for example, it acts chiefly upon the nervous system, and later upon the muscles. Although no evidence is forthcoming, there are strong probabilities that it affects in no small degree the molecular changes in serous membranes, and thus is added a new factor to its rapidly increasing list of physiological manifestations.

The well-known eliminative functions of the *glandular system* naturally point to it as one of the principal channels for the elimination of mercury, and this is confirmed by clinical observation; but it possesses no property aside from its influence upon cellular activity that would entitle it to be classed as a specific glandular stimulant. It is therefore somewhat *misleading to call mercury a specific sialagogue*, since we can trace the tissue-change to the effects of the remedy as a protoplasmic poison upon the cells concerned in elimination, and, fortunately for the scientific basis of therapeutics, the necessity for which this study is intended to develop, the foregoing admitted facts practically wreck the so-called "alterative" theory, viz., that "alteratives are remedies which improve the nutrition of the body without exerting any perceptible action on individual organs."

In compliance with the request of the writer a discriminating study, scientific and practical, covering the *physiological action of mercurials upon the liver and its functions*, has been placed at his disposal for the present article by Dr. William H. Porter, of New York, as follows:

"The action of mercurials upon the hepatic function is exercised in three successive characteristically distinctive stages, namely, as *stimulants*, as *cholagogues*, and as *depressants*.

"As the mild chloride or calomel possesses all these qualities to a marked degree, it is perhaps the best example by which to elucidate the complete action of mercury upon the hepatic and digestive functions. The blue mass and the gray powder act in the same manner, but, if anything, are a little less active. The bichloride has a similar action, but its more irritating properties make it less valuable, or even useless, as a cathartic principle. Still, it can be used as a powerful hepatic stimulant, and as an adjunct to the cholagogue action of calomel.

"The exact *modus operandi* by which mercury in any form produces the wonderful results upon the system that have been attributed to it for ages, has always been more or less in doubt, for the lack of a logical explanation; yet the most sceptical, after watching the effects of a few doses of this drug upon the human system, cannot deny the power and utility of mercury. Taking the stand that the inorganic compounds are not destroyed within the animal organism, no time need be wasted in speculation regarding the decomposition of any of the mercurials into other compounds. How, then, shall the action of mercury and its compounds be explained? Calomel, for instance, is almost insoluble; consequently it in itself is comparatively non-irritating to the intestinal tract. At the same time it is known to be one of the most active cathartic compounds of mercury—two almost contradictory propositions. The cholagogue action of calomel cannot be explained by any direct irritating action which it can produce upon the alimentary tract, through the increased peristalsis, by reflex irritation causing an increased flow of bile.

"The non-irritating character of calomel is just what gives it its chief power. Passing along down the alimentary tract without producing irritation, it is steadily absorbed into the entero-hepatic circulation and carried up to the liver. At this point of the animal economy the mercurial appears to act like a foreign body, and the hepatic cells, by their selective action, pick up the little particles of calomel from the blood, and eject them into the capillary bile-ducts. In accomplishing this task the hepatic cells are called upon to perform more work, and if the amount of calomel passed through the liver is small, its action is simply to stimulate the organ to a little greater activity. For a time the hepatic cells secrete a little larger quantity of bile, and such as has a little better quality. Up to this point the calomel has only been stimulating and physiological in its action. If now the calomel be administered in larger quantities—either by frequently repeated small doses or in one large dose—the eliminating action of the hepatic gland is greatly augmented. At the same time the protoplasmic elements which constitute the hepatic cells are stimulated, by the passage of this foreign body through their substance, to a more active production and elimination of the bile-acids.

"When sufficient calomel has reached the liver to produce this copious flow of bile-acids, the acids are discharged into the capillary bile-ducts more rapidly than they can react upon the alkaline phosphates or carbonates, and form the normal and neutral bile-salts. When this hypersecretion of the bile-acids is established, a cholagogue action is developed. This action, however, can only be temporary in character, because the protoplasmic vitality of the hepatic cells will, in a comparatively short time, be exhausted. After this excessive production of the bile-acids and their discharge together with the calomel, there is a period of protoplasmic exhaustion in which the bile-producing function of the liver is held in abeyance.

"Viewed in this light calomel and its class of mercurials may be stimulating, cholagogue, and depressing in their action upon the functions of the hepatic gland—one condition following in quick succession after the other. The rapid intestinal peristalsis and frequent discharges from the bowel, however, are not the direct result of the mercurial action, but *a secondary effect* which has been brought on by the irritating properties of the bile-acids, so copiously discharged into the intestinal canal—as just shown. This fact is established by the lack of cathartic action by calomel in cases of occlusion of the common bile-duct; and furthermore, by the counter-test that where bile-acids are administered medicinally, a brisk, cathartic, and cholagogue-like action is at once established.

"The hypersecretion of the bile-acids and its consequent effect upon the intestinal tract is not in any sense a physiological action, but is strictly a pathological process. But, by developing this abnormal condition in the functional activity of the hepatic gland, the liver-cells are stimulated to perform an abnormal amount of work, often vicarious in its nature, and by which the cells are empowered to expel many abnormal and by-products from the system—a task which, in their normal condition, they are absolutely unable to perform. In this manner Nature rids herself of many foreign and offending substances which, if allowed to remain and multiply within the system, would, in a short time, destroy the animal vitality, a result too often seen in cases imperfectly treated.

"The period of inaction which is imposed upon the hepatic cells as a sequel to this excessive action gives the protoplastic elements a chance to rest and to imbibe a more serviceable nutritive pabulum—thus augment-

ing their nutritive activity and enhancing their functional vitality. When the hepatic cells again resume their physiological work, they are in a condition of high nutritive tone, and consequently the secretory and excretory work of the liver is more perfectly effected. The intestinal and hepatic transmutation of the food-elements is more perfectly accomplished; and, as a natural sequence, all the nutritive processes of the body are intensified; secretion and excretion in general are more perfectly performed, and the animal vitality is raised to a higher standard. If the system has been poisoned by any form of microbic or ptomaïnic toxine, or is the seat of any inflammatory action, toxic or otherwise, the organism is, by the above-described processes, placed in the best possible condition to destroy the etiological factors and remove the resulting pathological processes, and thus restore everything to a normal condition.

"By a somewhat similar physiological action the well-known antiphlogistic power of the mercurials can be explained; and following this method of action for the mercurials generally, ptyalism, and all that class of toxic symptoms produced by mercury and its compounds, can be rationally explained. The same reasoning also shows clearly that the size of the single doses has little, if anything, to do in determining the liability to mercurial salivation. If, from any cause, the hepatic cells are inactive, and thus fail to respond to the presence of the mercurial salt, and to eliminate as speedily as it reaches the hepatic gland, then the mercurial will pass over into the general circulation, where, finally, the salivary glands will attempt to perform the work of elimination that should have been accomplished by the liver-cells. In like manner, when the calomel is given too freely, or when opium is given to check the cathartic action, and the hepatic cells either become exhausted from over-taxation, or they are retarded in their action by the opium, when the mercurial passes into the general circulation. Thus, again, the toxic symptoms with salivation will be produced. So long, however, as the hepatic cells retain their selective and excretory activity, it is absolutely impossible to develop the toxic symptoms of mercury. The use of enormous doses may become the cause of exhausting the hepatic cells, whereupon poisoning will, of course, ensue.

"From this study of calomel and its allied preparations, the belief is entertained that all mercurial preparations act in a similar manner, if of any value; that the specific effect of the mercurials in syphilis is simply due to the augmented hepatic function produced by the elimination of the metal. The more irritating preparations, in so far as they act at all, act in the same way as calomel, but if taken in too large doses, are so locally irritating that they become poisonous in themselves. Therefore mercury is indicated in all cases where it is necessary to increase the functional activity of the liver and aid this organ in eliminating not only more bile, but also poisons of all kinds, microbic, ptomaïnic, leucomaïnic, katabolic, and vegetable or animal in origin."

In contrast with the foregoing somewhat optimistic views concerning the therapeutic virtues of mercurials should be quoted the remarks of Budd ("Diseases of the Liver," 1846): "The frequent use of mercurials in functional hepatic complaints may lead to much mischief. When the liver has become accustomed to the stimulus of mercury, no other medicine will sufficiently excite its action. The person is then led to the habitual use of the medicine, and, after a time, the constitution is undermined by it. It increases the activity of the liver at first, but seems to leave it weaker than before, and, if frequently resorted to, the nutrition of the patient, impaired by the original disease, is still further impaired by the drug."

It will not be out of place to insert here the opinion of Thomas King Chambers, of London ("The Indigestions," third American revised edition, Philadelphia, 1870, p. 377), long and favorably esteemed as an authority on digestive disorders, as follows:

"The superstitious use of mercurials is very singular. They are supposed to make the alvine excretion normal, though the only visible result is its becoming more abnormal with each dose. They are supposed to do good by 'acting on the liver,' whether the liver is acting too little or too much. They are supposed to 'act on the liver,' though it has been shown by Dr. Scott's experiments ('Beale's Archives,' vol. i., p. 209), that the quantity of bile is not increased, nay, it is rather diminished when mercury is taken. All that the metal can be really seen to effect on the hepatic function is a poisoning of the bile, so as to prevent absorption by the ilia, and to cause the secretion to be rejected in excess and in a liquid form *per anum*, and that is a very doubtful advantage to most invalids.

"The only effect at all desirable following mercurial purgation, and which in fact seems to constitute for patients the attraction to its use, is the relief of certain cerebral symptoms, giddiness, muscæ volitantes, dark globes in the sight, singing in the ears, etc., which result from excess of venous over arterial blood in the brain. It acts in this case as a destructive upon the venous blood, and adjusts the balance by subtraction. Time after time, as the rough experiment is resorted to, the strength is lessened by it, and as the necessity for its use appears greater, more and more subtraction is required. The good and true way of restoring the circulation to its normal condition is by addition, by increasing the supply of new-made blood to the arteries."

In order to reconcile the differences existing between the views held now and those which obtained twenty-five or forty years ago, it should be noted that a generation ago practitioners had no true conception of the physiological effects of comparatively small doses, all dosage being determined by promptness in effect which, being followed by depressant manifestations, was very properly condemned.

While in the preceding remarks but little has been said of the *antiseptic properties of mercurials*—their value in this direction being inferred—it will be appropriate to consider this principle more fully than can be done in the section on Therapeutics. Undoubtedly mercuric chloride, owing to its actively poisonous character, stands at the head as a general antiseptic. Other drugs are of equal value as regards their power to destroy bacteria, but none of them seems to possess the same degree of antipathy toward the spores of bacteria: hence, when these spores are removed from contact with ordinary antiseptics and transferred to a suitable soil, they again multiply as rapidly as before. The favorable results attending the employment of less powerful antiseptics than the bichloride in surgical practice may be credited to the method of using the solutions freely, whereby the spores are carried off along with the *débris* and other foreign substances that would act as irritants and thus favor subsequent infection. And to this latter cause (irrigation) may be ascribed the beneficial effects of sterilized water. On the other hand, oily substances like creolin, lysol, and Peruvian balsam, owe their antiseptic virtues in part to the fact that they take up and cling to foreign substances, thus interfering with the reproduction of spores by preventing them from being lodged in a proper soil; the latter is an important factor in determining the vitality of spores as well as that of the bacteria themselves.

Again, it has been found that comparatively weak solutions will prevent the development of bacteria, while much stronger solutions are required to kill developed bacteria, all of which is graphically shown in the accompanying table, compiled by N. de la Croix, and for the most part confirmed by Koch (Brunton: "Pharm. Ther. and Mat. Med.," third edition, 1888, p. 91). (See p. 625.)

The hypodermatic employment of mercurials, popular with some, but strongly condemned by many, is advocated on the ground that curative effects in syphilitic lesions are produced more speedily than when the drug is given by the mouth or by inunction, and besides, that the digestive functions escape serious derangement. According to the investigations of Winternitz, when mercury is given by interstitial injection, elimination is effected principally through the kidneys; and he has also demonstrated that the percentage of the drug thus

excreted remains unaffected whether soluble or insoluble preparations are used, and that potassium iodide, even in substantial doses, exercises no influence upon elimination through the renal structures. The advocates of hypodermatic medication have, as yet, advanced no plausible explanation of the increased advantages therefrom, and its acceptance on the part of the profession will be referred to in the section on therapeutics. (See "Surgical Practice.")

The popularity of inunctions may be accounted for from the fact that mercury thus administered finds its way into the circulation in the form of extremely fine particles—without running the gauntlet of the liver—and its therapeutic effects are thereby enhanced in the same manner as when the drug is taken internally after thorough trituration. *Vaporization* also produces more distinct effects, probably for the same reason, but both methods are open to objection, since the amount actually introduced cannot be definitely measured or determined, and it requires the closest scrutiny to discover evidences of toxicity before serious harm results to the patient. It is doubtful if any considerable difference exists ultimately when mercury reaches the general circulation, whatever mode of administration is adopted.

SUMMARY.—Having now, in a general way, completed the study of mercurials, beginning with the gross lesions which attend acute poisoning, and following up with an investigation of their effects upon the brain, heart, liver, kidneys, etc.; and commented relative to their influence upon the blood, the tissues, the protoplasmic cells, oxidation, secretion, and elimination, when given internally, subcutaneously, by inunction, or vaporization, it seems as though nothing more could be said which would add to our present knowledge concerning the wonderful effects of this drug. And yet notwithstanding the abundant testimony brought forward to account for the effects witnessed, and the tentative suggestions advanced relative to its influence upon cellular activity, there is nothing, absolutely nothing offered which enables us to determine with any degree of scientific accuracy just how therapeutic results are obtained. There is still lacking an important link to complete this chain of evidence before the employment of mercury can be said to rest upon a strictly scientific foundation.

Perhaps an inquiry concerning its *action as a sorbefacient* will throw some additional light upon this mysterious and hitherto unexplained problem. To say that the effects of mercury are due to "*catalysis*," "*specific*," or "*selective*" action, or to assume that the "*hypothesis of interference*" is sufficient to account for them, is merely to substitute one unknown quantity for another. For example, with our present knowledge, we can understand and explain the causes which conspire to affect the pulse, temperature, and respiration; and we can also follow its action upon the functions of the liver, the kidneys, the skin, the alimentary tract, the salivary glands, and buccal mucous membrane, since these organs and structures are concerned in eliminating the poison; but how shall we demonstrate its sorbefacient properties in removing fibrinous exudations, syphilitic deposits, iritis, pericarditis, and inflammatory reactions of a benign character, without at the same time admitting that the drug may have some deleterious or untoward effect upon the organism as a whole? The only probable explanation of this paradox which suggests itself is based upon the assumption that in moderate dosage, the irritant (stimulant) action of mercury suffices to increase metabolism—*indirect or constitutional effects*—and that like all other poisons, it will be eliminated by those channels which are best adapted for the purpose—*direct or local effects*. The so-called "specific" action, "elective" action, or "catalytic" action on morbid products and diseased conditions, is nothing more than an incidental physiological effect, dependent upon the well-known properties of all poisons to manifest a disposition to associate themselves with retrograde changes—mercury not excepted.

The therapeutic study of mercury is therefore narrowed down to a consideration of *two principal factors*,

namely, the indirect or constitutional influences (*consequential benefits*), and the direct or local influences exerted upon functional or pathological disturbances (*physiological benefits*). This discovers the secret of the successful employment of all remedies, organic and inorganic, which are poisonous in themselves or foreign to the organism, and each has its value in certain directions, each has its limitations in all directions. When this value is overrated, or these limitations exceeded, harm invariably attends its administration. Our future triumphs in therapeutics, therefore, lie in the direction of studying, not alone the modifications affected by disease upon cell-life and cell-function, but the same strict rules must be applied to the reconstructive metamorphosis resulting from the employment of remedial agents, as has been done in the case of mercury, a remedy which, by its action upon cellular activity, removes and dissipates fibrinous exudations, syphilitic deposits, iritis, and pericarditis; which corrects the derangements of cell-function incident to inflammatory reactions, all phenomena bearing upon its therapeutic value being in perfect harmony with pathological study and physiological observation.

THERAPEUTICS.—In preparing the therapeutic section, the writer has aimed to give expression to the trend of modern practice in the use of mercurials, and to this end has incorporated under various sub-headings personal communications from recognized authorities in their respective departments. Such reports are, in many instances, more representative than a summary by a single writer, and in the following arrangement, which is intended merely to cover the principal disorders to which the drug is adapted, these contributions will be the means of guiding the student toward a true conception of its proper place in the physician's armamentarium.

Gastro-intestinal Affections. — Notwithstanding the harm which has attended the use of mercurials in this class of disorders, they undoubtedly possess distinct therapeutic virtues which entitle them to confidence; but in order to accomplish good, they must be exhibited with intelligence and discrimination, the conditions being clearly indicated in the following remarks by Professor Andrew H. Smith, of New York:

"Mercurials may be employed in gastro-intestinal affections with one of three objects, namely, to simply move the bowels, to excite hepatic and glandular secretion, and as anti-ferments.

"For the first purpose, calomel is the agent generally employed. It acts, probably, by increasing the flow of bile—which itself is a cathartic—and by stimulating the intestinal glands. This is a fair inference, from the fact that the purgative effect of calomel is not increased, but rather diminished, by giving large doses. A dose of several grains is sufficient to produce a large outflow of bile, and if more is taken the excess seems to act mechanically, like bismuth, to stay the cathartic action, rather than as a local irritant to the mucous surface. Short of producing a cathartic action, mercurials are much employed when there is evidence of deficient hepatic and glandular activity, such as is afforded by a furred tongue, a bad taste in the mouth, headache, anorexia, etc. Small doses are sufficient for this purpose, and they seem to influence cell-action in the epithelial as well as in the glandular structures. It is remarkable what an effect a single dose of a fraction of a grain of calomel will have in removing the 'patchy' condition of the tongue, so often observed in gastro-intestinal disorders.

"As intestinal antiseptics, mercurials are of great value, especially calomel and the bichloride. It is probable that the first becomes to some extent changed into the second. The efficiency of the bichloride as a germicide, in attenuated solution, is universally recognized. Indeed, it has been suggested that the whole mass of the blood might be rendered sterile by non-poisonous doses of this agent. Be this as it may, the intestinal disturbances attributable to ptomaines, generated in the digestive tube, are often relieved with remarkable promptness by remedies of this sort."

From the foregoing, therefore, it is evident that these remedies will be serviceable in the treatment of such disorders as gastric ulcer, gastro-intestinal catarrh, and to a certain extent in nearly all cases of diarrhœa and dysentery. As a purgative, calomel is mostly used when the immediate effect is desired, while in cases that do not require this effect, and when the object is to reach distant organs, one of the more irritant preparations (biniodide, protoiodide) may be given. Occasionally, during the progress of disease, sometimes in the early stages of febrile affections, a single substantial dose of calomel may be helpful. It requires a nice discrimination, however, to determine the conditions which demand a large dose of calomel for its purgative effects. To quote Thomas King Chambers: "Some call this clearing the decks for action; in a majority of instances, they may be said to throw overboard much of the best tackling on the ship and loosen her armor-plates."

In typhoid fever, calomel in small doses is unquestionably of benefit, but large doses, or its continuous administration as a routine practice should be condemned, since other remedies, safer to the patient, better for the disease, are now at our command. In all subacute and chronic cases, when the hepatic function is below par, the most striking results will attend the judicious employment of the biniodide in small doses (gr. $\frac{1}{100}$ two or three times a day).

Hepatic Disorders.—Mercury has long been recognized as a useful remedy in that morbid complexus known as "*biliousness*," and when administered in dosage that precludes the possibility of after-depression, it appears to be quite serviceable, although it is contra-indicated in acute congestion of the liver. In passive congestion, on the contrary, small doses of mercury—calomel or the biniodide in solution—will promptly produce beneficial effects. It is a mistaken notion that mercurials are of value in hepatic abscess, gall-stones, acute yellow atrophy, but they are of some temporary service as adjuvants in jaundice. It is doubtful if mercurials have any therapeutic value in hepatic cirrhosis, but they may be of service in ascites associated with this condition for their constitutional effects. Selwass (*Berlin. klin. Wochenschr.*, 1888, No. 38, p. 762) reports favorable results from the employment of calomel when treatment is begun in the early stages, although, even when combined with the use of digitalis, the disease is not cured. In a total of ten cases, only the recent ones (5) were benefited by the treatment.

Dujardin-Beaumetz advises a combination of calomel and corrosive sublimate as *an hepatic stimulant*—gr. jss. of the former and gr. $\frac{1}{3}$ of the latter—and this, with the addition of arsenic, is a favorite formula with Dr. William H. Porter (New York). On the whole, however, small doses of corrosive sublimate (gr. $\frac{1}{200}$ hourly) with suitable adjuvants, will generally accomplish all the good that can be gained from these large doses, and thus the depressant effects are avoided. In adults suffering from passive congestion of the liver, hæmorrhoids, and tenesmus, with or without bloody stools, these small doses produce magical results.

Diseases of the Kidneys.—The use of calomel as a diuretic was recommended some years ago, and has attracted considerable attention. The objection to its use, however, lies in the fact that it must be given in sufficient dosage to produce stomatitis, which requires active treatment in the way of gargles; and sometimes diarrhœa follows, making the use of opium necessary, and for this reason the beneficial effects have been questioned. It is especially advocated as a diuretic in œdematous conditions associated with cardiac disease, and it is said that, when continued for a sufficient length of time in the healthy subject, it produces in from two to ten days distinct diuresis, a condition similar to that which obtains from the subcutaneous employment of corrosive sublimate and the inunction of blue ointment. It is claimed that the subcutaneous injections act most powerfully as diuretics, the inunctions least, while the internal administration produces an effect about midway between the two. Small doses have no diuretic effect; only medium and

large doses increase the amount of urine. The somewhat doubtful claim has been put forward also, that calomel given under these conditions not only diminishes, but cures pathological changes in the kidneys. Biegarski (*British Medical Journal*, June 22, 1889) is of the opinion that cardiac dropsies are even more amenable to this treatment when corrosive sublimate is given subcutaneously, less to mercurial ointment by inunction, and that in dropsy due to kidney disease and obstruction of the portal circulation, the mercurials are of very little use; all of which confirms the view advocated by Nothnagel a year or so previously.

Various theories have been advanced to account for the diuretic action of mercurials in cardiac disease, when this does not obtain in renal disease proper, although in health the diuretic action is perceptible. Jendrássik suggests that calomel causes absorption of the dropsical fluid by the blood, while Fürbringer believes it is due to an irritation of the renal epithelium by the mercury; but neither of these theories appears to be satisfactory. There is reason to believe that increased oxidation (cellular activity) is an important factor—previously referred to—and that the determination of calcareous matter in the kidneys may likewise exercise an irritant (stimulant) action upon the epithelial cells of the convoluted tubuli, these cells being principally concerned in the elimination of solids (Heidenhain); and the elimination of mercury itself would fall within this latter category.

Phthisis.—In anæmia occurring as a result of phthisical dyscrasia, Dochmann (*Therap. Monats.*, September, 1888, p. 415) claims that calomel has a rapidly favorable action, even when iron has failed, since it improves the appetite, regulates the bowels, and corrects menstrual difficulties. The dose recommended is, gr. $\frac{2}{3}$, three or four times a day, the medicine being discontinued for several days at the expiration of five or six days. A recrudescence of the fever demands an increase of the daily dose for a time. Martell (*Prag. med. Wochenschr.*, 1888, No. 25) also reports good results from the same method. The latter authority advocates the employment of calomel topically as well as internally and by inhalation. Of course, in those cases where the tubercular process is of an indolent character, the increased oxidation resulting from the employment of mercury cannot be other than beneficial (consequential and local benefits); but it can have no direct influence upon the bacilli. Given in small doses and not too long continued, it stimulates cellular activity.

Syphilis.—As an indication of the conservative tendencies in the employment of mercurials in syphilis, it should be noted that Mr. Jonathan Hutchinson, the veteran syphilographer, now advocates the employment of gray powder (*hydrargyrum cum creta*), in one-grain doses, three to six times daily, one grain of Dover's powder to be given twice a day to control the bowels; but unfortunately the opium is extremely objectionable, since it involves ultimately the treatment of two diseases instead of one. There is no doubt of the curative action of mercury in syphilis, but in times gone by it has too often been accomplished at the expense of the patient's health, owing to the unnecessarily large doses administered, facts very fully brought out by the observations of Professor Edward L. Keyes, of New York ("Trans. International Medical Congress," September, 1876), whose positive conclusions are as follows:

"1. Mercury is an antidote to the syphilitic poison, and of service in controlling all its symptoms in all (even the latest) stages of the disease, its power over gummata being least marked and not to be relied upon.

"2. Mercury in minute doses is a tonic.

"3. Iodine cures certain symptoms of syphilis, but does not prevent relapse.

"4. The use of mercury, long-continued, uninterruptedly, as far as practical, in small doses, from the time of the earliest eruption, constitutes the best treatment of syphilis."

In connection with the above may be mentioned the views of Professor William Osler, of Baltimore (private communication) on this important topic, as follows: "Of course, we all know the striking influence of the mercurials in relieving the blood-condition of syphilitic cachexia, but here, I think, the action is undoubtedly similar to quinine in malarial cachexia, not so much a direct action upon the blood as a neutralization of the poison and natural restitution of the corpuscles."

Mercurials are also of value in non-specific as well as in the specific forms of *skin diseases*, the indications for their employment being deducible from our previous conclusions.

Ophthalmology.—The following concise report from Professor Samuel D. Risley, of Philadelphia, practically covers the employment of mercurials in ophthalmology:

"In ophthalmological practice I esteem mercury of great therapeutic value. There are large groups of diseases in which no other drug is so useful, and this is true not only of those forms of eye disease where syphilis is the important etiological factor, but also of affections of the uveal tract, and in certain forms of corneal inflammation not traceable to this disease. It is used without hesitation in all forms of plastic iritis, in exudative choroiditis, neuro-retinitis, etc., whether of known specific origin or not. My experience would seem to suggest that, as a matter of course, this drug should be administered in recognized syphilitic cases, whether occurring along with other secondary symptoms or associated with the later manifestations. It can be administered either in the form of the corrosive sublimate, in small, frequently repeated doses, by means of inunction, or the mercurial bandage.

"In acute forms of disease, as in plastic iritis, inunctions pushed to the point just short of ptyalism are to be preferred, the patient meanwhile being confined to his bed. In chronic forms of inflammation, *e.g.*, interstitial keratitis, corrosive sublimate is employed, or, instead, the bandage worn around the waist night and day, and kept well covered with mercurial ointment. Not infrequently, I employ the well-known formula of potassium iodide and corrosive sublimate, but this combination seems best adapted to cases of neuro-retinitis than to other forms of eye disease."

Diseases of the Throat and Nose.—As expressing the views of practitioners in this special department of medicine, the following report from Dr. George B. Hope, of New York, will prove interesting and suggestive:

"As a class, hypertrophic derangements of the mucous and submucous areolar tissues are so peculiarly resistant to the usual range of topical applications as to discourage all such measures, and lead to a resort to surgical or destructive agents in order to overcome the effects of structural changes. However applicable this may be under certain favorable conditions, there are yet cases where this course is neither rational nor practicable, and it is in these instances that a remedy addressed through constitutional channels offers the only prospect of relief. Iodide of potassium and mercury furnish the most striking types of active cellular-therapy agents, and from this standpoint—eliminating the former on account of its unfavorable action to the mucous membrane—the indications for mercurial treatment may be considered to be definitely established. As an illustration may be cited a case of simple, chronic, hypertrophic laryngitis, in which the ventricular bands were so far involved as to offer a serious obstruction to respiration, with the surrounding parts in accord with the prominent pathological condition. Under the administration of full doses of the protoiodide of mercury, a speedy and satisfactory resolution was obtained without the introduction of any auxiliary line of treatment.

"In a word, if the theory of mercurial action is correct in its clinical details—that it encourages the oxidation of loosely-formed cell-elements, and stimulates their elimination by the lymphatics—it would seem that the legitimate limits for its administration, aside from syphilitic affections, are particularly covered by conditions representing the imperfectly organized type of inflammatory exudation, as in (chronic) infiltration of the intercellular tissues, or the thickening of the epithelial layers, as in

moderate pachydermatous laryngitis—features of chronic catarrh."

Nervous Diseases.—From Dr. Wharton Sinkler, of Philadelphia, the writer has received the annexed report, which fairly comports with views already advanced, and in a large measure confirms them from the clinical standpoint.

"In regard to the employment of mercurials in nervous diseases, will say that in organic diseases of the brain and cord, when due to syphilis, of course, mercurials are of prime importance. It does not follow, however, that all scleroses of the spinal cord are benefited by the administration of mercurials, even in those cases where there is a clear and undoubted history of syphilitic infection together with secondaries. Locomotor ataxia is an illustration of the truth of this observation. A large proportion of the cases of tabes with which we meet have a more or less distinct history of syphilis, some writers asserting that as many as seventy or eighty per cent. of tabetics have had this disease. Notwithstanding this fact, few cases of locomotor ataxia are benefited, even by the most vigorous course of mercurials and iodide of potassium. On the other hand, some of the other forms of syphilitic infection of the nervous system yield promptly and completely to mercurials and iodide of potassium. Those cases which are spoken of as syphilis of the brain and cord seem particularly ready to yield to mercurial treatment; and in this class of cases mercury seems to be of more value than the 'mixed treatment,' or the iodide of potassium alone.

"For some reason, *mercury by inunction* gives better results in the treatment of syphilis of the nervous system than when the remedy is given by the mouth. I have had comparatively little experience in the use of mercury hypodermatically, but recall one patient suffering from spinal sclerosis with a specific history, who made very marked improvement under the use of the bichloride of mercury administered hypodermatically.

"In the treatment of nervous syphilis, I have not found it necessary to push mercurials to the point of salivation, and in one or two cases where I accidentally salivated patients, there was no apparent benefit to the nervous disorder for which the mercury had been given. As a rule, I find it preferable to give mercurials in conjunction with iodide of potassium, but frequently I administer it alone. In some of the forms of sclerosis of the cord, not due to syphilis, small, alterative doses of mercury are of great value. Usually, the remedy is to be persisted in for a number of months, and it is best to give it in small doses. I prefer in these cases to give the bichloride, as I think it is less likely to disturb the stomach and intestinal tract, and it is borne for a longer period of time than the other preparations of mercury. As a general nerve-tonic in some of the functional nervous disorders, mercury is of considerable value, more especially, I think, when it is combined with arsenic and iron.

"There are some forms of *headache*, especially those of specific origin, in which small doses of the bichloride of mercury are very useful. In the severe nocturnal headaches of syphilitics, one one-hundredth of a grain of this salt, repeated hourly, will sometimes afford relief. *Cerebral and spinal meningitis* are treated most effectively by the administration of mercury; and calomel or gray powder seems to answer better in meningeal inflammation than any of the other mercurial salts, as it is necessary to get a prompt and speedy impression."

Obstetrics.—In obstetric practice the use of mercurial solutions (bichloride, 1 to 5,000) has largely given place to carbolic acid, creolin, and lysol, and other less toxic substances for the vaginal *douche* and intra-uterine applications. Indeed, the employment of any antiseptic is strongly condemned as both useless and dangerous in uncomplicated labors. In 1889, Garrigues (*American Journal of the Medical Sciences*, August, page 109) published a synopsis of twenty-two cases in which death occurred from the use of corrosive sublimate solutions, and at that time he favored creolin solutions (two per cent.) as a substitute for mercuric chloride.

Corrosive sublimate injections in *ordinary midwifery cases* need not be practised, but the solutions may be used for the disinfection of the outer surfaces of the patient, for the hands of nurses and physicians, and for all materials brought into contact with the patient. When intra-uterine medication is demanded, the strength of the solution should not exceed 1 to 5.000 to 10,000, and the injections should not be given more frequently than twice in twenty-four hours, although the vaginal *douche* may be given as often as every three hours; and at the time care should be taken that no symptoms of absorption arise, and for which the physician must be constantly on the outlook. Upon the first appearance of toxic symptoms, the medicament must be immediately discontinued until all danger has passed. As the bichloride combines with impurities in the water as well as with albuminous principles and alkaloidal poisons, and is seriously affected by alkaline fluids, it has been suggested that it might be prepared in concentrated form with glycerine and hydrochloric acid dilute, from which solutions could readily be prepared.

By the use of antiseptics and the adoption of measures looking to asepsis, the *septic death-rate* in American maternities has been reduced to less than one per cent. Intoxication from the intra-uterine *douche* has been of such frequent occurrence that a suggestion is offered to the effect that hydrogen dioxide solutions be substituted, on account of the latter being harmless to patient, efficient as a destroyer of unhealthy tissues and discharges, cleanly and perfectly manageable, and, withal, prompt in action. Owing to the rapid oxidation which takes place when the dioxide is brought into contact with morbid products, in using it for the intra-uterine *douche* care must be taken that the outflow is not obstructed, since the gas generated might be sufficient to force morbid material into the tubes, and thus defeat the purpose for which it was used.

Concerning the employment of mercurials internally against syphilitic infection, the following brief report from Dr. Joseph Price, of Philadelphia, will be read with increasing interest, since it furnishes a demonstration of their almost universal value:

"I have for years used mercurials freely in *syphilitic child-bearing and pregnant women*, also in syphilis of the new-born. The iodides are of but little value, except in the management of symptoms, and in the tertiary stage in mothers. At present, I have a number of mothers under treatment continuing from periods of two to nine years; some of them have borne as many as three healthy children in that time, no symptoms reappearing in either mother or offspring."

Diseases of Children.—Mercurials find a wide range of application in the treatment of diseases peculiar to childhood and infancy, although indications point to the probability of their too liberal use in some cases. Albeit their value is not denied, there are many instances where other and more efficient medicaments may be substituted, so that in them alone does not lie our only hope. For example, in *croup* and *diphtheria* mercurialization really accomplishes no good purpose, and besides, we have other remedies that can be used as adjuvants, which are more effective and entirely free from the dangers arising from mercurialization. The routine method of treating diphtheria should be remodelled upon a scientific basis corresponding with our present knowledge concerning the life-history of the pathogenic microorganism associated with it. Clinical observation is opposed to emetics in both croup and diphtheria, the two being so closely connected that it is difficult to say positively where the one ends and the other begins.

By many, calomel is given as a preliminary in diphtheria to produce some effect upon the bowels, when corrosive sublimate is substituted, but this course must be followed with caution, because in the serious cases absorption may be interfered with to an extent that will prevent or delay the manifestations of mercurialization, when constitutional symptoms rapidly supervene. It is doubtful if, in such cases, the mercury be of any service; nay, indeed, clinical experience is against the production of a factitious disease.

The *medicinal treatment of diphtheria* should be conducted with two principal objects in view, viz. : (1) To arrest the rapid multiplication of germs, and (2) to counteract the pathological changes effected by their products. For the first, an *anti-biotic* is required, to render the soil unsuitable for their growth; and for the second, an *anti-toxine* is demanded, to fortify the system against the morbid products. Unfortunately, mercurials cannot be used in sufficient dosage, with safety to the patient, to accomplish either purpose. *Locally*, the mercurial preparation must not be too readily soluble, and should not too easily combine with albumin or other substances which destroy its antiseptic value. *Internally*, diffusibility is desirable, and with the recent introduction of new compounds it is hoped a better and more efficient therapeutics will be instituted. In this connection should be mentioned an interesting and valuable analytical report by Dillon Brown, covering 2,368 patients in whom intubation was practised, with 647 recoveries, or 27.3 per cent., and including from his own personal experience 115 cases, all seen in consultation. Of the latter number, 50 had not been subjected to the bichloride treatment, and the recoveries were 24 per cent. ; in the other 65 cases, with bichloride, 36.9 per cent. recovered. Stellden, a Swedish physician, reports 1,400 cases of diphtheria treated by mercury cyanide, with but 69 deaths (approximately, 5 per cent.), while the usual rate of mortality in his district has been 92 per cent. The method of using the cyanide consisted in adding to gr. $\frac{1}{8}$ mercury cyanide, half a drachm of tincture of aconite and two ounces of honey, and of this mixture the patient takes a teaspoonful at intervals of an hour or less. In addition to this, a gargle—1 to 10,000 mercuric cyanide and peppermint-water—is employed every fifteen minutes.

The following comprehensive *résumé* by Professor Mary Putnam-Jacobi, of New York, very fully embodies the practical adaptation of mercurials in this class of cases :

"The position of mercurial preparations in the nursery has varied greatly within the present century. At one time vaunted under many forms, as specific for many ailments or serious diseases; at another, almost completely condemned ; they have recently been reinstated to a considerable extent in the *armamentarium* of the family practitioner. The list of cases in which mercurials are to-day employed is not, indeed, long ; but each disease on the list is important and of frequent recurrence.

"The revival of mercurial medication, perhaps, principally depends upon the modern demonstrations of the great antiseptic power of mercury, and especially of its most poisonous salts, as the bichloride and the biniodide. Coincidently has been demonstrated the microbic etiology of such diseases as diphtheria, and the occurrence of fermentations due to microbes in gastro-intestinal disorders. The utility of mercury in syphilis was well established by clinical experience before syphilis, as an infectious disease, had been referred, like other infections, to microbic inoculation. Although the precise infecting agent of syphilis has even yet not been isolated, its existence is unhesitatingly assumed ; and with as little hesitation are the curative powers of mercury attributed to the antiseptic virtues of the drug.

"In the great *epidemics of diphtheria* which raged in France in the first half of this century, Bretonneau used calomel extensively and pushed it to the point of salivation. The result was disastrous, as was, indeed, every other form of treatment used in these terrible times. From about 1850–53, calomel was altogether abandoned, and tincture of iron and powerful stimulation adopted in its place. Quite recently, however, has been introduced, in addition to such stimulation, the internal administration of minute doses of bichloride of mercury, especially when croup is threatened ; the use of sprays of solutions of bichloride, 1 to 4,000 to 6,000 of water ; finally, fumigations of calomel in croup, both before and after tracheotomy or intubation. One milligramme (gr. $\frac{1}{65}$), per hour, may be administered for one or two days to even very young children, and in association with tincture of iron given throughout the hour. It does not, as has been occasionally asserted, cause depression ; and it certainly does not cause salivation. Of course, like all other remedies in this dreadful disease, it often fails to cure. The spray can also be used once an hour. The fumigations are made by burning ten grains of calomel on a tin plate in the bed where the child is lying, while this is surrounded by a blanket to retain the fumes. In ordinary *non-specific laryngitis*, the same small doses of corrosive sublimate, or else hourly powders of calomel, gr. $\frac{1}{12}$ each, will often arrest an attack in a day or two.

"What is the precise mode of action of the gray powder (hydrarg. cum creta) in *acute gastric catarrh*, is by no means well known ; but empirically, its efficiency cannot be doubted. In *fermentative diarrhœa*, the bichloride, combined with bismuth and the carminative oils, is more useful. Even in adults, hourly doses of gr. $\frac{1}{60}$ of bichloride are extremely efficacious for this disorder, the poisonous drug seeming to neutralize the poisons which are forming in the intestinal tract. The same dose may also be given to children.

"The time-honored method of giving a dose of calomel for the so-called *bilious attacks* of children, as of adults, is also again revived. In children these attacks generally mean gastro-duodenal catarrh with extension to the mucosæ of the bile-ducts. Calomel certainly increases the flow of bile, even in healthy animals—more probably its secretion ; under increased pressure this is able to force its way through the ductus choledochus—occluded by swelling—and the free passage of the secretion initiates the reduction of the swelling.

"*The points to remember* in all these gastro-intestinal diseases is, that the mercurial is to be administered for a comparatively brief period—two or three days at the outset—and not to be relied upon for prolonged use, nor to be frequently resorted to in states of chronic indigestion ; that is, if the conditions recur, and tend to become chronic. The old method of an occasional blue-mass pill is insufficient for the purpose ; other treatment is coincidentally required to stimulate the sluggish portal circulation.

"In *dysentery*, fractional doses of calomel, combined with ipecac and opium, although an old, is a still justly accredited mode of treatment. Its value is increased when associated with the newer method of systematic irrigation of the bowels. The *so-called method of Law*, originally applied to peritonitis, by which calomel, $\frac{1}{2}$ grain, was administered hourly, is still valuable, for in this way much more of the drug can be introduced into the system than when it is given in massive doses—or, possibly, a larger amount is converted into bichloride, and thus becomes a potent disinfectant to the putrid contents of the intestine.

"No opposition has ever been raised to the administration of mercury in *infantile syphilis*, except by the fanatics that profess to cure adult syphilis without mercury. The bichloride, Van Swieten's liquor, is a convenient form, and can frequently be tolerated for a long time without causing gastric irritation. If this occur, the medication must, of course, be interrupted, or replaced by mercurial inunctions. These, as well as bichloride baths—grains vij. to a bath—are well suited for the cutaneous and articular lesions of syphilis. Citrine ointment, diluted four times, is best adapted for syphilitic vegetations around the anus and genitals. The mercurial treatment should be continued, with interruptions at intervals of six or eight weeks, for a period of two years."

Surgical Practice.—A full discussion of the antiseptic properties of mercurials in surgery does not properly come within the scope of this article, and it will be sufficient to refer briefly to the methods now in vogue, and which are set forth in the annexed communications. It should be stated that the value of corrosive sublimate as an antiseptic may be modified by various conditions, namely, *temperature, albumin, bacteria, and light in the presence of organic matter*, so that although immediately available, its power for good may not long remain, and thus a false sense of security is given the surgeon. Professor N.

Senn, of Chicago, expressed his continued confidence in it as follows:

"I have tried many substitutes, but always fall back upon corrosive sublimate. I use for disinfection of hands and field of operation, a 1 to 1,000 solution; for disinfection of infected wounds, 1 to 1,000 to 10,000."

Professor Roswell Park, of Buffalo, who seems to have followed closely the teachings of Sir Joseph Lister, is favorably impressed with the mercury-zinc cyanide. He writes as follows:

"Mercuric chloride and mercury-zinc cyanide I ordinarily apply or employ in my surgical work. The latter comes very near being an ideal antiseptic, in my estimation. When either of these is used with judgment, it is capable, I think, of giving the greatest satisfaction. Still, I think we have now so many antiseptic drugs to choose from, that one may succeed in any branch of surgical work *without* using mercurial preparations. This is especially true since *aseptic* methods have been introduced. Indeed, every operator learns to place reliance on one or two drugs for this purpose in accordance with his training, his surroundings, or his personal idiosyncrasies. I do think, however, that we could dispense with mercurials as antiseptics, were we compelled to, without perceptible loss.

"For occasional internal use, as intestinal antiseptic agents and general alteratives, it does not seem to me that we could make substitutions without serious loss.

"The mercury-zinc cyanide solutions which I employ are usually 1 to 2,000. Compresses are used wrung out of a solution, 1 to 500. For disinfecting hands I ordinarily use hydrogen dioxide in full strength. Instruments I boil, usually in a two per cent. soda solution. For the hands I use green soap with five per cent. lysol, and after that, frequently, the permanganate bath with bleaching in oxalic-sodium hypophosphite solution."

Hypodermatic Medication.—Calomel by intra-muscular injection was first used by Scarenzio as early as 1864, but owing, perhaps, to the faulty methods and lack of antiseptic precautions, it was not brought prominently to the attention of the profession until advocated by Neisser, of Germany (1885), who in 1888 modified Lang's formula for "gray oil." By the observance of strict antisepsis, it is said, abscesses are of rare occurrence. Wilson (*Medical News*, vol. lii., 1888, p. 593) reports twelve cases treated (sixty-nine injections) with very satisfactory results. A grain of calomel, rubbed up with glycerine (℥ xv.), to which is added at the time the operation is performed a few minims of recently boiled water, and thoroughly shaken, constitutes the medicament. These injections are given at intervals of a week or ten days. In a private communication to the writer, dated March 10, 1893, Dr. Wilson says he has continued to use the treatment in proper cases since that time without modification of importance.

Lang's original formula (*Brit. Med. Jour.*, June 16, 1888) for *gray oil* (oleum cinereum) is as follows:

Mercury,	
Lanolin	each 3 parts.
Olive oil.....	4 parts.

M. Sig.: For hypodermatic use; contains thirty per cent. of mercury.

The dose of gray oil is 0.10 to 0.15 c.c., introduced deep into the back or nates every five to eight days. Neisser's modification (*oleum cinereum benzoinatum*) is given herewith:

Mercury.....	20 parts.
Liquid paraffin.....	40 parts.
Benzine-ether	5 parts.

M.

One cubic centimetre contains about six grains of mercury. The dose is 0.25 c.c. at the same periods as the gray oil, and treatment is interrupted from time to time. When resumed, smaller doses are used, and the injections practised more frequently, as it has been found that the small dose at short intervals is better than the large dose at longer intervals. The gray oil can also be used as a topical application at points affected by the specific poison —bone disease, specific disease of the larynx and nares. It is claimed that the gray oil subcutaneously has shown special benefits in cases where the disease affects the ear, the Eustachian tubes, or the forehead.

Lang has published the following conclusions: "(1) Gray oil is efficient with the least dosage of mercury; (2) it is convenient for both patient and physician; (3) dangers of reaction are but slight; (4) no abscess has attended several thousand injections; (5) can be employed in all cases where a mercurial is indicated; (6) can be used in the immediate neighborhood of syphilitic lesions."

Watraszewski (*Archiv für Dermatologie und Syphilis*, 1889), in comparing the therapeutic adaptation of calomel, yellow oxide of mercury, and gray oil, gives a decided preference to the yellow oxide in the dose of two-thirds to one grain. Mucilage is preferred as a vehicle for the following reasons: (1) It can be made of proper consistence to hold the powder in suspension; (2) it has no local irritating effect; (3) it does not decompose the mercurial salt; and (4) it excites no general disturbance.

Notwithstanding the favorable evidence in favor of these preparations, the probabilities are that corrosive sublimate is more extensively used in this country than any other mercurial for hypodermatic medication.

Dr. Yvert, of Paris, some years ago submitted to the Academy a note on the value of the *bichloride as an anti-cholera vaccine*, giving in evidence an account of forty-five patients so treated in Tonkin, with nine deaths (twenty per cent.), while the mortality in that section of Asia averaged sixty-six per cent. The dose administered ranged from one-third to two-thirds of a grain, when the patients were seen within twenty-four hours after the first manifestations of the disease. As a prophylactic it proved efficient.

Topical Applications.—For boils and felons the citrine ointment is usually recommended, but it is less efficient than the biniodide, 1 part to 10 of benzoinated lard. The affected area should be covered with a thin layer of the ointment, and allowed to remain for two, three, or four hours, according to the tenderness of the skin, when it is thoroughly removed, internal medication being depended upon to complete the absorption. Mercurials are used as caustics in specific ulcerations and chancroids, but in ordinary cases they have been supplanted by other more acceptable products. As previously noticed, the oleate is very generally employed, and by means of ingeniously constructed instruments a powder can be deposited in the urethra in the treatment of urethritis.

Mercurial inunctions have lately been more favorably received than hypodermatic injections in the treatment of syphilis, and at the recent Paris Congress there appeared to be a strong sentiment against the latter method, some going so far as to assert that it was dangerous. It is said the method has been abandoned by Schuster, Kaposi, Julien, Fournier, and others, who have all returned to the earlier methods. *John Aulde.*

METHACETIN (Para-oxymethy-acetanilide). This compound is a derivative of acetanilide, introduced in 1888 by F. Manhert as a substitute for phenacetine, to which it is closely allied. Its formula is $C_6H_4OCH_3$-$NHCH_3CO$, which differs from acetanilide, C_6H_5NH-CH_3CO, by substituting for one atom of H one atom of the oxymethyl group OCH_3. In phenacetine, $C_6H_4OC_2$-H_5NHCH_3CO, the ethyl group replaces the methyl group of methacetin.

It forms in white, glistening, scaly crystals, without color or faintly reddish; odorless; melting at 127° C.; it has a slightly bitter saline taste; is soluble in water at 60° F., 1 part in 530; in boiling water it dissolves in 12 parts; is freely soluble in alcohol, chloroform, glycerine, and fatty oils. Methacetin possesses antipyretic, antiseptic, and analgesic properties similar to those possessed by phenacetine, which it resembles therapeutically, as well as chemically. The advantage claimed for it over

all other antipyretics is its freedom from toxic effects or any injurious action on the blood-corpuscles. It is said not to cause any depression, malaise, tinnitus, or any of the lesser annoying symptoms. It is recommended particularly for children and enfeebled persons. The only unpleasant effect is the production at times of free perspiration. Further experience has shown that it is not so devoid of these unpleasant symptoms as is claimed, as in addition to the profuse sweating, it occasionally causes very decided symptoms of collapse. It is, however, the most harmless of similar antipyretics.

It has proved very serviceable in typhoid fever, typhus, pneumonia, phthisis, and all febrile diseases. It produces a rapid fall of temperature, sometimes in fifteen or twenty minutes. The fall usually reaches its minimum in about three hours, remains stationary for about an hour, and then rises rapidly. With small and more frequently repeated doses the temperature may be kept low, but not at an apyretic point. The action of the drug also varies according as it is given with the daily rise or fall of the fever, and its most marked action occurs when it is given to act with the normal decline. In typhoid fever its effect is also more decided in the latter periods of the fever with the remissions than during the continuous stage. Its power of lowering temperature is also evident during health. The dose is from two to three grains, to be repeated in three or four hours if required. Larger doses of five and seven grains are frequently given when a rapid and decided effect is required.

In acute rheumatic fever and painful febrile troubles, as pleurisy, etc., five-grain doses prove very satisfactory in reducing the swelling, pain, and fever. As an analgesic in neuralgia and migraine it has not proved as useful as phenacetine and acetanilide. Although its employment is accompanined by fewer unfavorable symptoms, it has not replaced phenacetine, which it most resembles in action, its antipyretic properties being less marked, and as an analgesic it has proved very much inferior.

Physiological experiments have proved that forty-six grains will cause death in a rabbit, producing spasms in the posterior, and later in the anterior, half of the body. After death there is found hyperæmia of all the organs, and the heart flaccid and filled with blood-clots. No hæmoglobin is found in the urine. *Beaumont Small.*

METHYL CHLORIDE (Monochlormethane). A colorless gas with a sweetish taste and an ethereal odor. It is soluble in one-fourth its volume of water, much more so in ethyl and methyl alcohol, and freely in ether and chloroform. The gas is not very inflammable; when ignited it burns with a greenish flame. At a temperature of −13° F., or under a pressure of five atmospheres, it is converted into a liquid, with a specific gravity of. 9915, neutral to test-paper. This liquid boils and becomes a gas at a temperature of −5.8° F., the change of condition being accompanied by the absorption of a great amount of heat. On account of the rapidity of this change an intense degree of cold is produced, amounting to a fall of 40° or 50° F. or more.

The use of this refrigerant action was applied by Débove, in 1884, as a local anæsthetic for neuralgia and other painful affections. It has been used in sciatica, pruritus, spinal pains after railway accidents, and in the painful joints of rheumatism, and in pleurisy. The duration of relief from pain is never prolonged or permanent; from one hour to three or four hours is the average. In the latter conditions the relief has not been satisfactory, and any such use is beyond the scope of the remedy. The most important application of this compound has been as a freezing mixture for the performance of minor surgical operations. It has been used with decided success in circumcision for phymosis, evulsion of toe-nails, excision of cancer of the lip, opening of mammary abscess, incision for empyema, and many similar painful procedures.

Methyl chloride is very extensively used for this purpose in the Paris hospitals, where it is prepared and stored in specially formed flasks, resembling those in which nitrous oxide is supplied. These are so arranged that the spray may be made to issue as required, without any trouble or waste.

A stream of the spray may be applied directly to the part, in an oblique direction, for one or two seconds, or it may be directed upon a tampon of wool which is surrounded by floss silk and covered by thin silk. The tampon becomes saturated with the liquefied gas, which rapidly evaporates and absorbs heat from the adjacent parts. This latter method is more suitable for the relief of pain; for operative purposes the spray is to be desired.

The first effect on the part is to render it pale and bloodless and insensitive; a continuance of the cold produces a dried, parchment-like appearance, and this is the time to operate. The application of the spray must be guarded, as it is not without its disadvantages. If it is used too long it causes death of the part, with vesication and eschars according to the depth and extent of the injury. Frequently, where the action has been only of short duration, the part remains red and tender for several days, Dr. S. E. Berezovsky made a number of experiments upon dogs to determine the local effect of the spray. They showed that, 1, a spray of two minutes' duration, when directed against intact integuments, produces complete anæsthesia lasting from fifteen to twenty seconds, the tissues remaining sufficiently soft to allow cutting; 2, a spray of five seconds' duration, while inducing a somewhat longer anæsthesia, freezes the skin to an inconvenient degree; 3, a seven-seconds spray gives rise to consecutive local congestion and inflammation; 4, a twenty-seconds spray causes sloughing of the tissues down to the muscular layer; 5, a convenient and harmless anæsthesia, induced by a two-seconds spray, can be easily prolonged up to five minutes by repeating the spray at short intervals; 6, sufficient anæsthesia of exposed bones can be produced in the same way; 7, the spray does not cause either gangrene or thrombosis of blood-vessels.

Methyl chloride is a decided improvement upon ether spray as a means of producing local anæsthesia, but it has a powerful rival in the recently introduced ethyl chloride, which is milder in action but equally efficient. The disadvantage of methyl chloride is its powerful and rapid action, which is difficult to control both in extent and degree.

It has also been suggested as an anæsthetic, and a mixture of ether and chloroform, saturated with the gas, was suggested by Richardson, but no advantage was apparent, and it has failed to receive much recognition.

Beaumont Small.

METHYLENE BLUE (Tetra-methyl-thionine Chloride). An aniline derivative, its formula being $(C_6H_3N(CH_3)_2CL)_2NS$. Chemically pure methylene blue occurs in small indigo-colored scaly crystals, with a bronze-like tinge and dark green in transverse fracture. Slightly soluble in water, forming a deep blue solution, which is changed by sulphuric acid to a dark green, and from which a strong potash solution throws down a dark violet precipitate. The methylene blue of commerce (ethylene blue O) is a double chloride of zinc, and tetramethylthionine.

This aniline product was introduced into medicine in 1890, by Drs. Ehrlich and Lippmann, as an analgesic of some value. Professor Ehrlich had investigated the action of the drug on nervous tissue as a staining reagent, and had demonstrated that it had a peculiar selective action on the axis cylinders of motor and sensitive nerves. Further experiments showed that when taken into the stomach, or introduced subcutaneously, it rapidly spread throughout the system and gave relief to all neurotic pains, and the pain in rheumatism of the muscles, joints, and tendons. A two per cent. solution was used, by means of which one grain was given hypodermically. It was also used in capsules, the powder being given in doses of 1½ to 4 grains; as much as fifteen grains were given in one day. No ill effects accompanied its administration, and no change in appetite, digestion, pulse, or any of the normal functions. The drug was absorbed very quickly, and a quarter of an hour after the smallest dose the urine be-

came a bright green, after two hours a dark green, and after four hours a dark blue. No albumin was present. In the saliva a bluish tinge was detected, but there was no discoloration of the mucous membranes or conjunctiva. The anodyne effect began in about two hours, and was gradually produced; it had no effect on any fever or inflammatory condition. When administered in full doses it is liable to produce symptoms of strangury and increase the amount of urine, for which powdered nutmeg has been used with success in Germany. Other observers have found it of value in nervous headaches, herpes zoster, alcoholic depression, migraine, and in the pleuritic pains of tuberculous patients. Doses of 2 to 5 grains have been given three times a day.

In the following year, 1891, Ehrlich and Guttman announced that the drug was also a remedy for malarial troubles. They were led to experiment upon this disease from the fact that the plasmodia of malarial disease was readily stained by this body, not only in prepared specimens but also in fresh blood. They used the remedy in two cases of malarial fever—one quotidian, the other tertiary. They found that the drug had a decided curative power over the disease; the periodical attacks ceased within a few days, and at the end of eight days all plasmodia had disappeared from the blood. A dose of 1½ grain was given ten or twelve hours before the expected attack, and repeated every two hours until five doses had been taken. The treatment should be continued for seven or eight days after all malarial symptoms have subsided. Other European observers have reported the results of a trial of this remedy, generally with less beneficial results; its action was uncertain and frequently failed. It, however, produced a cure in many instances with different observers, and proved particularly useful in neuralgic pains of a malarial origin. Laveran experimented with it without obtaining any success. He injected it into the blood of pigeons affected with the hæmatozoön, and although the color was seen in the blood no effect was exercised upon the parasites. He also treated two patients affected with the disease, without influencing the paroxysms or destroying the malarial organism.

Dr. W. S. Thayer, in *Johns Hopkins Hospital Bulletin*, May, 1892, gives a detailed report of seven cases treated by this method. He concludes that—1. Methylene blue has a definite action against malarial fever, accomplishing its end by destroying the specific organism; but it is materially less efficacious than quinine, failing to accomplish its purpose in many cases where quinine acts satisfactorily. 2. Reaction appears to be rapid, the chills disappearing on the temperature, in remittent cases, falling to normal during the first four or five days; but later, however, if a sufficient number of organisms have resisted the drug, they appear to develop again directly under its influence, causing a return of the symptoms. 3. Methylene blue seems to have no advantages over quinine which would warrant its further use.

Methylene blue has also been given in tuberculous conditions. In pulmonary phthisis a dose of 1½ grain was given the first day, increased on the second day to 3 grains, on the third day to 4½ grains, and so on until 24 grains were given in the twenty-four hours. The usual improvement of symptoms is said to follow its use. In tuberculous pharyngitis the powder may be applied to the affected part, and in scrofulous glands of the neck, and for irrigating empyemic cavities a ten per cent. solution has been used. A solution of the same strength has also been recommended in diphtheria.

Beaumont Small.

METHYLOL. This compound is the dimethylate of methylene, $CH_2(OCH_3)_2$. It was first prepared by Malagati, in 1839, and suggested as an anæsthetic. Its use as such has not been adopted on account of its rapid evaporation, and its less agreeable effects than chloroform and ether. It is prepared by distilling a mixture of methylic alcohol, sulphuric acid, and peroxide of manganese; the product is formiate of methyl and methylol. By agitating this with caustic potash the formiate of methyl is destroyed without attacking the methylol. It is a limpid, very mobile liquid, specific gravity, .855, with a burning, aromatic taste. Its odor is penetrating, and recalls that of chloroform and acetic ether. It dissolves in three parts of water, in alcohol, ether, and the fixed and volatile oils. It boils at 107.6° F. and its vapors are not inflammable.

It has recently been introduced as an hypnotic. Its first effect is a transient period of excitement, followed by a deep and quiet sleep. It augments the heart-beats, slightly lowers the blood-pressure, and causes slower and deeper respirations. It leaves no bad after-effects. It is advised in all cases of insomnia and restlessness due to cerebral anæmia or inanition, and is contra-indicated in cerebral hyperæmia. It has been suggested that its hypodermic use is superior to other methods of administration—one and one-half minims in ten minims of water—but this has been found to prove irritating. The dose is from fifteen to thirty minims, which may be increased to one or two drachms; it is very pleasantly combined with syrup of orange-flower and water.

It has been employed extensively as a soporific in mental diseases, and found to be very useful in all conditions, except the commencement of simple mania. A tolerance is established, if its use is persisted in for any length of time, and the dose must be increased or the medicine stopped for a few days. It has also been found of service in the insomnia of delirium tremens. Professor Richardson found it of service in angina pectoris, when combined with amyl nitrite, in the proportion of nine parts to one. It lessens the rapid action of the amyl nitrite and prolongs its effect. It has been found to relieve the spasms of strychnine poisoning; its antidotal action is of no value if large quantities of the poison have been taken, but it is said rather to hasten a fatal termination under this condition.

It is used as a local anæsthetic in the form of an ointment—one part to six of almond-oil in simple cerate.

Beaumont Small.

MICROCIDINE. An antiseptic preparation introduced by Dr. Berlioz, of Grenoble, which is prepared by adding to fused naphthol-beta half its weight of caustic soda, and allowing the mixture to cool. It should contain seventy-five per cent. of naphtholate of soda, the remainder consisting of mixed naphthol and phenol compounds. It is a whitish powder, soluble in three times its weight of water, yielding a brownish solution. It is a powerful antiseptic, very slightly toxic, is not caustic, and does not injure instruments or clothes. It is said to be weaker than sublimate, but is ten times more powerful than phenol, and twenty times more powerful than boric acid. A solution of three parts to the thousand is used as a lotion and to prepare dressings. Under its influence, ulcers and suppurating wounds heal quickly, and disagreeable odors are checked. A solution of the same strength may be used for irrigating the bladder, uterus, and suppurating cavities.

It may be employed as an internal remedy in doses as high as thirty grains a day. It does not produce any irritating effect. The urine is rendered strongly antiputrescent, its action being similar to that of salol, but less irritating to the kidneys. *Beaumont Small.*

MICROSCOPY, CLINICAL. This article is intended to supplement the article "Microscopy, Clinical," by Dr. George Wilkins, Vol. IV., p. 775. As a large number of staining methods, etc., for bacteria are described in the articles "Histological Formulæ, etc.," and "Bacteriological Technology" (in the present volume, pp. 77 and 424), the reader is referred to these for further information.

Microscope and Accessories.—Bacteriology forms so important a factor in clinical medicine that a microscope provided with some sort of sub-stage condenser and homogeneous immersion lens has become indispensable. Wide-angled dry lenses, such as AA and DD Zeiss, on account of their superior illumination, are gradually replacing those with narrower aperture. For clinical work

the expensive apochromatic objectives are not necessary.

With the increasing demand for accuracy of methods, the habitual use of the micrometer, camera lucida, polariscope, microspectroscope, etc., is becoming more general.

A rack-and-pinion coarse adjustment and mechanical stage are very convenient adjuncts in working with high powers. In selecting a mechanical stage, one which can be manipulated by the left hand alone is to be preferred.

Of nose-pieces (revolvers), one with sockets for three lenses should be selected when both bacteriological and anatomical work is to be done, as then some combination of lenses like AA, DD, and $\frac{1}{12}$ Homog. will suffice for all purposes without having to change objectives.

Microphotography has not yet become sufficiently simplified to be of much use in clinical work. It is preferable to have a separate microscope stand, with sliding nose-pieces, constantly set apart for this work alone, and kept always ready for use, as the amount of time required in adjusting and centering the apparatus before a single negative can be taken is greater than that required to photograph a dozen different objects when everything is in readiness.

Light.—None of the substitutes for daylight, so far available, can be considered satisfactory, but the incandescent light, the electric light, the albo-carbon light, or the use of a blue glass screen sufficient to neutralize any excess of yellow rays, renders working with artificial light less fatiguing to the eye.

Reagent Bottles.—The dropping-bottles recently introduced, where a pipette stopper is ground into the bottle and fitted with a rubber cap, cannot be too highly recommended for convenience and cleanliness (Fig. 424).

Fig. 424. Dropping-bottle with Rubber Cap for holding Reagents.

Labels.—Small sheets of gummed paper, which can be cut or torn into any shape or form desired, effect a great saving of time and trouble as compared with ordinary labels.

Forceps.—The blunt-pointed, self-closing, forceps, devised by Cornet, are extremely convenient for working with cover-glass preparations. With these it is impossible to lose track of the smeared side of the cover slip (Fig. 425).

Fig. 425. Cornet's Forceps for Cover-glass Preparations.

Reagents. — *Fixing and Hardening.*—For giving accurate results, two fluids are specially to be recommended: 1.—Alcohol in the strength of ninety to ninety-six per cent., and 2.—Flemming's fluid, made by mixing 4 parts of two per cent. osmic acid solution, 15 parts of one per cent. chromic acid solution, and 1 part glacial acetic acid. This fixes in two to four days, when, after thorough washing in water (five to twenty-four hours with frequent changes), hardening can be completed in alcohol.

Corrosive sublimate in a saturated watery or alcoholic solution also gives good results, but does not penetrate deeply into the tissues.

Pieces of tissue to be treated by Flemming's solution should not be more than one-twelfth of an inch thick. The use of *bichromate* solutions is to be avoided where the structure of nuclei is to be studied, as these become materially altered in solutions like Müller's fluid.

Section Cutting. — Sections may be cut fresh in the freezing microtome, in which case it is best to avoid the use of gum, etc., for embedding. The sections can be received in one-half per cent. salt solution, and either examined unstained or else placed for one to two minutes in Loeffler's methylene blue, washed, and mounted in glycerine. To fix the blood in tissues the specimens should be thrown into boiling water for a few seconds previous to freezing. It is better to keep a small microtome specially for cutting frozen sections than to use the freezing attachments furnished with the sliding microtomes.

For obtaining sections of hardened tissues, a sliding microtome of the Thoma-Jung or Weigert-Schanze model is necessary. Those made by Bausch & Lomb are cheap, and give excellent results.

For sharpening microtome knives the attachment furnished by Jung will be found invaluable to those who (like the writer) have not naturally the gift of sharpening instruments. By having the razor blade mechanically held at a proper angle, no one, however unskilled, can fail to sharpen his knife satisfactorily.

Fig. 426.—Attachment for Microtome Knives, by which the blade is held at a constant angle while stropping. (Jung.)

Under proper conditions, sections of tissue only 10 to 15 μ in thickness should be obtained at each cut. When time is of value, the tissue, after a few hours' hardening in strong alcohol, may be clamped between pieces of hardened amyloid liver or elder pith, or, better still, glued to a cork by *Meyer's glycerine jelly.* This is prepared by mixing 1 part of gelatine, 2 parts of water, and 4 parts of glycerine, over a water-bath till thoroughly dissolved. Take a lump of the jelly as large as a pea, melt it upon the blade of a hot knife, and after transferring to the surface of a cork, press the tissue to be cut into it. As soon as the surface hardens place in absolute alcohol for a few hours. This method is preferable, as a rule, to the use of the freezing microtome, when a few hours' delay is admissible, as fixed tissue stains far better than fresh, and the definition of the nuclei is much sharper.

For delicate tissues, or very thin sections, embedding in paraffine or celloidin should be employed. (See "Histological Formulæ, etc.," Supplement, p. 424, and "Histological Technique," vol. iii., p. 658.)

In *staining* specimens the method of staining each section or series of sections upon the slide has come into very general use. A few drops of the (filtered) dye are poured upon the slide and allowed to remain until under a low power the nuclei can be distinctly seen as deeply colored points. Then, after washing with water, a few drops of absolute alcohol are allowed to remain for a few seconds in contact with the section, and then replaced by a few more. In this way the section becomes dehydrated in less than a minute, and can be clarified by dropping on a little xylol before mounting in xylol-balsam. Should the xylol produce turbidity, it is due to the fact of some moisture being still present, and alcohol must again be dropped on. With complete dehydration after treating with absolute alcohol the section may be rapidly dried with blotting-paper, and xylol-balsam applied at once, omitting the step of clarification. With picro-carmine apply a drop of glycerine without washing the section. By carrying out the staining on the slide itself all unnecessary handling of the specimen is avoided, and time is saved.

With *sections cut in paraffine* it is well to first attach the section, still in paraffine, to the slide (or cover-glass) by smearing on the thinnest possible film of a filtered solution of equal parts of egg-albumin and glycerine, (which may be kept indefinitely in a stoppered bottle by adding a small piece of camphor). On the slide, or cover-glass so prepared, the section is spread out with a soft brush. By heating the slide for a few seconds over a flame or water-bath, till the paraffine is seen to melt, the albumin will be coagulated and the section will adhere firmly to the glass, and can be manipulated with the same ease as cover-glass preparations. Staining can only be accomplished after removing the paraffine by xylol followed by alcohol and water, in the following order: (1) xylol, (2) alcohol, (3) alcohol again, (4) water, (5) stain. Sections cut in celloidin can be fastened to the slide by simply pressing upon them firmly with folded filter-pa-

per. When a series of sections has to be attached in a definite order, a slide should be first coated with a thin layer of collodion and allowed to dry; then the sections, moistened with alcohol, are placed in position and are partly dried with blotting-paper and covered with a second layer of collodion, the section thus lying between two layers of collodion.

A useful method of obtaining very thin (1 to 5 μ) sections from objects embedded in paraffine, is to coat the surface of the block with a layer of thin collodion just before each section is cut. This thin film of collodion will prevent even the thinnest and most brittle sections from falling to pieces.

The methods mentioned above for paraffine and collodion have long been practised in connection with normal histology and embryology, but are only now beginning to be appreciated by pathologists.

Examination of Blood.—The estimation of the percentage of hæmoglobin present is a point which should never be neglected in connection with the microscopic examination of blood. The hæmoglobinometer or hæmometer of von Fleischl has come into very general use, owing to its simplicity as compared with those of Hayem and Malassez. In estimating the amount of hæmoglobin the cell is filled with water, and one of the small capillary pipettes, filled with blood, is mixed with the water on one side of the partition in the cell. The colored glass plate is then moved until when beneath the uncolored half of the cell it gives the same depth of tint

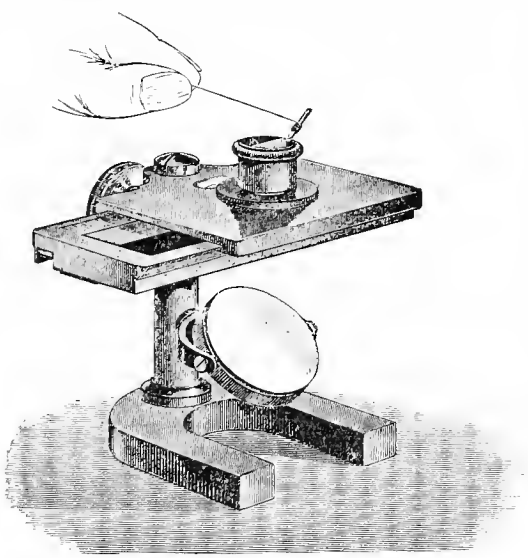

Fig. 427.—Von Fleischl's Hæmometer.

as the diluted blood; the reading on the scale then gives the percentage of hæmoglobin. The light used should be gas or petroleum, not daylight. The instruments usually record a little too high, but are accurate within about ten per cent.

A more exact and scientific method would be to determine the intensity of both the red and the yellow tints separately in the blood, by the use of standard tints (Lovibond's scale), as is done in water analysis, but no apparatus has yet been contrived for this purpose.

Graeber has arranged the following table as giving the diagnostic results of blood examination, but it is looked upon by other observers as being too arbitrary:

Hæmoglobin.	Number of red cells.	Diagnosis.
Reduced.	Reduced.	Simple anæmia.
Reduced.	Normal.	Chlorosis.
Reduced, but increased relatively to number of red cells.	Greatly reduced.	Pernicious anæmia.

Poikilocytosis and occurrence of nucleated red cells is commoner in cytogenic than in secondary anæmias but may occur in all forms of anæmia, leucocytosis, or leukhæmia.

Hæmatokrit.—Daland (*Univ. Med. Magazine*, March, 1892) has described a method of estimating the volume occupied by the corpuscles and deducing their number from this. He employs a centrifugal machine. The blood, diluted with an equal volume of 2.5 per cent. bichromate of potassium solution and thoroughly mixed in a watch-glass, is drawn into a glass tube 35 mm. long and having a calibre of 1 mm. The tube is closed at each end by a rubber cap and rapidly rotated until the mass of corpuscles which collects at the periphery attains a constant volume (with the above solution a constant volume is reached after about ten thousand revolutions, requiring about seventy seconds' time).

The tube is scaled in fifty parts, and therefore to express the volume of corpuscles in percentages, it is necessary to multiply the number shown on the scale by four. The volume per cent. in normal blood is 51.6 for red, and one per cent. for white corpuscles, making the value of each volume per cent. about 100,000 red cells, so that $51 \times 100{,}000 = 5{,}100{,}000$ per cubic millimeter, a number corresponding closely to that obtained by means of the hæmocytometer.

Ehrlich's Method.—A new method of examining blood is that of Ehrlich, based upon the affinity for basic and acid anilin dyes, of certain minute "granulations" found in the colorless corpuscles. The blood must be spread in a very thin film upon cover-glasses, and fixed by heating at a temperature of 120° C. This is best attained by using a flat brass bar placed over a petroleum oil stove, and, when a constant temperature is attained, placing the cover-glasses a little nearer to the flame than the point at which a drop of water is found to boil. To give good results, heating for from one to two hours is necessary. The writer has employed a mercury bath upon which the cover slips are floated, the temperature being controlled by means of a thermometer.

In staining, Ehrlich at first employed a solution composed of aurantia, indulin, and eosin, each 2 grammes; glycerine, 30 grammes; but the stain he now recommends is composed of saturated watery solution of orange, 125.0; concentrated solution of acid fuchsin in twenty per cent. alcohol, 125.0. Mix, and add alcohol, absolute, 75; saturated watery solution of methyl green, 125.0 (*Biondi's reagent*).

As the action of this stain is very variable, and as it is very difficult and tedious to obtain the right proportion of each dye, it is advisable to obtain it ready made, either in powder or solution, from Grübler, of Leipzig, or from his agents, Eimer & Amend, New York.

The staining is complete in from two to five minutes, when the superfluous dye should be washed off, the cover-glass dried with blotting-paper, and the specimen mounted in xylol balsam. In a successful specimen the nuclei are stained greenish, the red corpuscles orange, the eosinophilic granules red, and the neutrophilic granules violet. As the results of the stain are uncertain and depend upon the exact temperature at the time of fixing, it is best to lay several cover-glasses on each side of the line which represents the boiling-point on the heated bar, in which case some of the specimens are sure to turn out well.

Ehrlich has described five forms of granulations found in blood which have each a specific staining reaction. They were named empirically at first as α, β, γ, δ, and ϵ granulations, but the only ones having pathological significance for human blood are:

The α or oxyphilic granulations, which have affinity for acid anilin dyes, such as eosin, acid fuchsin, or picric acid.

The γ or basophilic granulations, analogous with those found in plasma cells (Mastzellen). These stain with basic anilin dyes.

The ϵ or neutrophilic granulations, which stain of an intermediate tint in a mixture containing both acid and basic anilin dyes. This form is the one most abundant in normal human blood.

The β or amphophilic granulations represent an ill-marked form intermediate between α and γ; the δ granulations, a transitional step between γ and ϵ.

In blood the following forms of colorless corpuscles occur:

1. Lymphocytes, 7 to 9 μ in diameter, about the size of red-blood corpuscles, with relatively large nucleus and small surrounding protoplasm. They resemble the white cells of the lymph glands, from which they are probably derived. They contain no granules.

2. Polynuclear leucocytes (neutrophiles), diameter double that of the lymphocytes; somewhat smaller than the mononuclear leucocytes; nuclei irregular in form, curved, S-shaped, or multiple; protoplasm filled with fine neutrophilic granules. Derived from bone-marrow.

3. Mononuclear leucocytes; larger than those last named; nucleus large, round, or oval. No granulations.

4. Eosinophilic leucocytes (eosinophiles); of same size or larger than the polymorphous neutrophilous nucleus; round or polymorphic. Protoplasm filled with coarse eosinophilic granulations. Derived from the bone-marrow.

Normal blood contains the above-mentioned varieties in about the following proportions (Erlich): Lymphocytes, twenty to thirty per cent.; polymorphic or neutrophilic leucocytes, sixty to seventy-five per cent.; mononuclear, six per cent.; eosinophilic, two to four per cent. (From 100 to 1,000 leucocytes should be counted in each case.) In addition, a few transitional forms are seen having a polymorphic nucleus, but with non-granulated protoplasm.

As far as has yet been determined the pathological significance of these cells is that—

1. In simple leucocytosis, or in leucocytosis accompanying the severe secondary anæmias following large losses of blood or other exhausting discharges, the number of white cells is simply increased, both absolutely and relatively to the red, without any marked disturbance in the relative proportions between the different forms of leucocytes.

2. In lymphatic leukhæmia the lymphocytes preponderate.

3. In splenic and splenic-myelogenous leukhæmia, there is no absolute increase of the lymphocytes, whose proportion, relatively to the total white cells, may fall to one or two per cent. Great absolute and relative increase of polynuclear forms. Great absolute but little or no relative increase of the mononuclear and eosinophilic leucocytes.

4. In purely myelogenous leukhæmia, great increase in eosinophile cells.

5. In splenic and myelogenous leukhæmia a special form of mononuclear cell appears, known as the myelocyte. This is larger than the ordinary leucocyte, and is filled with fine neutrophilic granules. It does not possess the power of amœboid movement.

6. In all forms of leukhæmia, and in both primary and secondary anæmias, the red corpuscles may show, besides diminution in number, irregularities in size and form (poikilocytosis = increased plasticity), and nucleated red corpuscles may be present. Erlich's method is admirably adapted for demonstrating nucleated red cells.

7. In slight degrees of splenic myelogenous leukhæmia, and during the remissions which occur during the progress of the disease, the condition may be diagnosed with certainty by (*a*) the relatively small number of lymphocytes, and (*b*) the presence of myelocytes.

There are now some bacteriological grounds for supposing that leukhæmia is an infectious disease due to a specific micro-organism.

When the blood is simply examined in the fresh or unstained condition it should be spread in the thinnest possible layer by using a perfectly flat slide and very thin cover-glass, and examined with a $\frac{1}{12}$ immersion lens. The presence of roulcaux of corpuscles shows that the film of blood is too thick to be of service.

A very good account of the application of Erlich's method is given by Dr. W. S. Thayer,* of Johns Hopkins University.

* Johns Hopkins Hospital Bulletin, 1891, and Boston Medical and Surg. Journal, 1892.

Biondi has introduced a special method for examining blood in sections. He recommends collecting a few drops of blood in 5 c.c. of a two per cent. osmic acid solution. After twenty-four hours the supernatant fluid is withdrawn by a pipette and the sediment embedded in liquefied agar-agar (five per cent.), which, after solidifying in a mould, is hardened in eighty-five per cent. alcohol and cut in the microtome. For staining, Biondi's reagent (see above) is suitable.

Malaria.—For the detection of the plasmodium malariæ Plehn recommends fixation of the cover-glass preparations in absolute alcohol for a few minutes, and staining in concentrated aqueous methylene blue solution, 60 c.c.; one-half per cent. eosin solution in seventy-five per cent. alcohol, 20 c.c.; distilled water, 40 c.c.; add 12 drops twenty per cent. caustic potash solution. The flagellate forms are stated to be stained by this method.

Laveran's method is as follows: The cover-glass is fixed by heating in the usual way, and stained first in a saturated watery solution of eosin, which is then dried off with blotting-paper, and a saturated solution of methylene blue allowed to act for about one-half to one minute. The flagellate forms do not stain well.

By either of the above methods the parasites are stained blue and the blood-cells pink. Care must be taken to avoid mistaking precipitation of the blue pigment in the red cells for the endoglobular parasites.

Some clinicians with large experience in the diagnosis prefer the direct examination of unstained specimens under a $\frac{1}{12}$ immersion lens to the staining methods (Osler, Celli). A striking feature in these unstained specimens is the very pale anæmic condition of those red cells which contain the parasites.

The method of making microscopic observations at body temperature by surrounding the microscope by a water-jacket having a glass front, which has recently become very general in laboratories, is simply a modification of a method in use by Sachs, many years ago (Fig. 428).

Sputum.—*Tubercle Bacilli.*—Of the large number of new methods published in the last few years, probably the most satisfactory is that known as Gabbett's method, by which the decolorizing and counter-staining of the specimen is combined in a single act by the use of a solution of two per cent. methylene blue in twenty-five per cent. sulphuric acid. After staining with Neelsen's carbol fuchsin (fuchsin, 1; alcohol, 10; carbolic acid, 5; water, 100), putting a few drops of staining fluid on the cover-glass and boiling it, by holding directly over a low flame for one-half to two minutes. The cover-glass is dipped in the acid methylene blue for one-half to one minute, washed, and examined. Although it is claimed that this method is practically the same as that of B. Fränkel, who decolorized and counter-stained simultaneously in a mixture of methylene blue, alcohol, and nitric acid, I have found that the Gabbett method invariably gives clean preparations free from granular precipitate, while Fränkel's method does not do so. The contention of Czaplewski, that fluorescin dissolved in alcohol or oil of cloves tended less to decolorize the tubercle bacilli than the treatment by alcohol, has been shown by Nuttall to be erroneous.

Nuttall * has devised an extremely ingenious and accurate method for estimating numerically the number of tubercle bacilli in sputum, but, unfortunately, the details and precautions to be observed are so numerous as to prevent it from being applied for ordinary diagnostic purposes. McFadyean and others recommend, where the bacilli are very scanty, that the film of sputum should be smeared upon a glass slide, instead of a cover-glass, as a larger field for examination is obtained in this way. The writer has found this modification of considerable service.

When only a very few bacilli are present the sputum should be liquefied either by Biedert's method of boiling with soda, or by allowing it simply to putrefy till quite fluid and then examining the sediment.

* Johns Hopkins Hospital Bulletin, 1891.

Heart-failure Cells.—In sputum of persons suffering from heart disease, with red induration of the lungs, E. Wagner has described as heart-failure cells certain large epithelioid cells containing brown hæmatin granules, and whose presence is significant of chronic pulmonary congestion, with dilatation of the capillaries. Recently other writers have made observations showing the diagnostic value of this sign. Although undoubtedly of service in establishing the fact of organic pulmonary change, when they can be found, the general utility of this phenomenon as a means of diagnosis is greatly diminished by the fact that it is impossible in nine-tenths of the cases of chronic heart disease to obtain any sputum at all.

Leprosy.—In cases of genuine leprosy a scraping from a leprous nodule, or a drop of blood from it, is invariably found swarming with enormous numbers of the lepra bacilli, which take the stain characteristic of the tubercle bacillus. There is no danger of confounding this condition with lupus, as in the latter disease the bacilli are extremely scanty or may be entirely absent.

The value of microscopic methods alone in the detection of tetanus, glanders, and diphtheria is limited, as

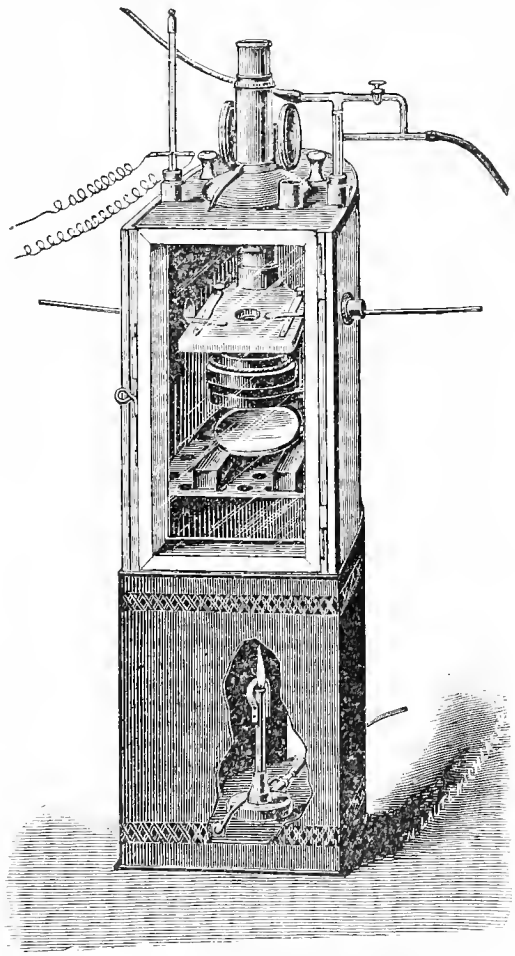

Fig. 428.—New Form of Warm Stage (Lautenschläger's), regulated by means of a thermostat.

the microscopic characters in these are not of themselves sufficiently distinctive to enable the diagnosis to be made with certainty, and culture methods must be employed.

Quite recently peculiar organisms have been described as occurring in typhus by Hlava, and other authors have described monad and coccidia forms in scarlatina, measles, small-pox, and syphilis, but their significance is still uncertain, owing to the want of uniformity in the observations of different independent observers.

Urine.—The recognition of casts, blood, etc., in the urine has been greatly facilitated by the introduction of Litten's centrifugue.

A small test-tube filled with urine is rapidly rotated for

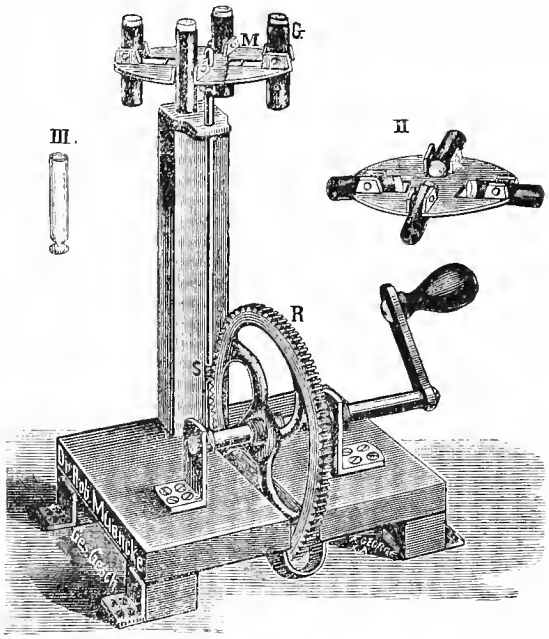

Fig. 429.—Litten's Hand Centrifuge.

about two minutes, at the end of which time the sediment will be found collected at the bottom. Where a deposit is very scanty the sediment of a quantity of urine may be collected by using tubes having a small constriction near the bottom. After rotating, so as to drive the sediment into the bulb at the bottom, the fluid in the upper part of the tube can be poured off, replaced by fresh urine, and again concentrated. The original contention that bacteria could in this way be collected from urine has not been found to be the case.

The recognition of tubercle bacilli in urine can be accomplished by the ordinary fuchsin and staining methods, but is very difficult when a small number only are present.

Fæces.—The recognition of the amœba coli has proved of great service in the diagnosis of tropical dysentery. This organism is found not only in stools, but in abscesses forming in different parts of the body, especially in the liver. Councilman and Lafleur, in a case of severe anæmia, without any intestinal symptoms, found enormous numbers of amœba coli to be present in the stools.

An important medico-legal bearing of the examination of fæces was recently brought out by Austin Flint, who, in a case of murder, where the interest centred on the question as to whether stains found on the clothing and beneath the fingers of the suspected criminal were derived from ordinary fæces or from the contents of the small intestine, proved the latter to be the case, by demonstrating the presence of bilirubin and tyrosin, which are normally found in the small intestine, but become decomposed in their passage through the colon.

The detection of typhoid bacilli in the stools has been found too uncertain and difficult to afford a sure indication of typhoid fever, even where culture methods are employed.

The detection of the cholera spirillum in the stools of acute cases can sometimes be made by the microscope alone, as this organism may be present almost in pure culture in the small, flocculent particles which occur in

the rice-water evacuations; but of course for scientific accuracy the use of culture methods is always necessary.

From the parallel arrangement of the comma bacilli Koch found (Zeitsch. f. Hyg., xiv., p. 319), in his laboratory, that a microscopical diagnosis was possible in fifty per cent. of the cases. In no instance was this shown to be erroneous by the result of the cultures.

Sporozoa in Malignant Tumors.—Besides the organism found in the blood of malaria (see above), lowly organized animal forms were found by Darien associated with Paget's disease of the nipple and molluscum contagiosum. The pathological significance and the precise position which these organisms occupy in the animal kingdom are not yet decided, in the absence of culture methods.

Cancer has been stated to contain sporozoic-like organisms, but their nature and significance are still a matter of dispute. For their detection sections should be prepared from tissues fixed in alcohol or sublimate, and stained with logwood and eosin or by anilin dyes, preferably saffranin. In sections fixed in Flemming's solution good results are obtained by Biondi's reagent.

Examination of Tissues.—*The microscopical diagnosis* of the tissues obtained at operations or autopsies has become an important part of clinical microscopy. In addition to the examination of teased specimens, sections prepared by the freezing microtome form the chief means of diagnosis.

In recognizing parenchymatous degeneration it is important to distinguish it from the granular appearance which is simply the result of post-mortem changes, and, as pointed out by O. Israel, the differential point to be attended to is the fact that the cell elements are swollen (cloudy swelling, but different from that observed as post-mortem change) and increased in size.

Virchow has recently called attention to certain pathological changes which can only be recognized with certainty by the use of the microscope. They are as follows:

1. Diffuse fatty metamorphosis of the interstitial cells in the brain, spinal cord, and nerves.

2. Parenchymatous and fatty metamorphosis of the muscles, heart-fibres, kidney, liver, and the parietal cells of the peptic glands.

3. Fragmentation of the heart muscle. This forms an extremely common and hitherto unrecognized alteration, which directly accounts for sudden death in a large number of cases. It can be best recognized in rather thick sections, either fresh or hardened in Müller's fluid.

4. Ganglion-like swelling of the nerve-fibres. Best recognized by drawing out the nerve-fibrils from their sheath and examining either directly in water, or in glycerine, after fixing in one per cent. osmic acid.

5. Calcification of the ganglion cells. Recognized by the presence of highly refracting, lumpy, angular, or rounded masses, which dissolve in weak mineral acids, with the evolution of gas.

6. Fat embolism of the lungs and kidneys. Recognized either by examination of fresh specimens, which can be prepared by snipping out small portions of the tissues with scissors, or better, by cutting sections of the tissues, after hardening twenty-four hours in Müller's fluid to which one-fourth bulk of osmic acid has been added.

7. White hepatization and red induration of the lungs. Recognized by the filling of the alveoli with small round cells in the first case, and by the presence of brownish hæmatin pigment in the walls of the alveoli in the latter.

8. The early stages of proliferation of the tissues. Recognized by the increase in the number of nuclei, especially the swelling of the endothelial nuclei of capillaries.

9. Slight degrees of amyloid degeneration. Recognized in sections by red reaction with methylene violet, or by a brown stain when iodine solution is employed.

In addition to these microscopical features the examination of tissues, fluids, etc., for bacteria, by both staining and culture methods, is often of very great importance. In many cases of otherwise unexplainable death the fatal issue is caused by septicæmia, due to the presence of one form or another of the septicæmia organisms (occasionally of the bacillus coli communis) in the blood. This auto-infection by bacillus coli is common in the later stages of both acute and chronic exhausting diseases, especially in those affecting the intestinal tract.

Thrombosis.—The presence of thrombi in the capillaries, with or without hyaline degeneration of the vessel walls, is a matter to which, recently, much pathological significance has been attached. The occurrence of the so-called liver-cell thrombi, detected first in the vessels of the brain by Jurgens, afterward in the smaller vessels of the liver by Klebs, is a phenomenon the explanation of which is by no means clear. It has been looked upon as explaining the fatal issue in cases of eclampsia.

Rabies.—Babes has recently stated that a rapid microscopical diagnosis of rabies may be made by cutting sections of the nerve-tissues which have been hardened in alcohol for several hours. The appearances considered by him to be characteristic consist of swelling of the nerve-cells, granular condition of the protoplasm, enlargement of the endothelial cells, and the occurrence of capillary ecchymoses. Although in the hands of an expert accustomed to histological examinations of rabic tissues, these appearances may be sufficiently striking, it is doubtful if the observations of ordinary microscopists, on this head, could be received with confidence. In any case, the inoculation methods should not be omitted, and diagnosis by the microscopic appearances alone should only be resorted to where the material at disposal has been received in spirit. The rapidity of the process, by which the diagnosis is completed in the course of a few hours, is, of course, a great point in its favor compared with the delay and uncertainty of inoculation.

Frozen sections of fresh brain or cord may be fixed by leaving for one hour in pure piridin (Goodall).

In the diagnosis of tumors which have been extirpated a chemical reaction has been described which appears of value. This consists in smearing the tissue with strong nitric acid, which causes connective tissues to swell up and become translucent, while epithelial tissues become an opaque yellowish-white color. As in this way infiltration of carcinoma in muscles, etc., can be definitely established in the course of a few moments without any microscopic examination, the method should be of valuable assistance to surgeons in extirpating cancers. Sarcomata do not show the characteristic reaction.

The diagnosis of decidual remnants in cases of suspected abortion is a matter of considerable importance. The villi of the chorion, when present in their typical branched form, with clump-shaped extremities, are highly characteristic. Sections of suspected tissues may show large, flattened endothelioid cells with distinct round nuclei.

The diagnosis of malignancy of tumors from the microscopic examination of small portions excised, is a matter which should always be undertaken with considerable caution. Although such fragments are usually sent to pathologists for diagnosis, far more valuable results could be obtained if the examination were made by those in charge of the case, as the signification of the microscopic appearances often depends more on the relations of the parts than on their histological type. In cases of suspected squamous carcinoma (epithelioma) it is well to bear in mind that, on the one hand, infiltration of the epithelial cells into the deeper interstitial tissues is not pathognomonic of epithelioma, but also occurs at the margins of lupoid ulcers; and, on the other hand, cases of malignant epithelioma occur, in which, in the early stages, no deep infiltration of epithelium has taken place. Butlin insists that chronic ulcers, occurring about the mouth, in which the surface is covered with squamous epithelium, should be regarded as malignant and treated as such. The writer had the opportunity of examining a case where the tongue was excised for a suspicious ulcer in a very early stage, and where, out of some hundreds of sections from all parts of the growth, none showed deep infiltration of the epithelium, though

the patient subsequently died from secondary epithelioma commencing in the submaxillary gland. Klebs insists upon the diagnostic importance of dilated lymphatic spaces in the submucosa beneath the epithelial layer for the diagnosis of cancer of the larynx.

Cornil is less inclined to place reliance, in the case of specimens obtained for diagnosis from suspicious erosions of the uterus, upon the relation of the epithelial tissue to the deeper parts than upon absence of the basement membrane, which he considers to be highly characteristic of carcinoma. In order to place reliance upon the absence of the basement membrane or the arrangement of the cells, however, it is necessary that the portions of tissue should be placed, immediately after removal, in strong alcohol and well hardened before cutting, as a delay of a few hours will so alter the appearance as to make an accurate diagnosis impossible.

The study of the cellular changes, especially the mitotic appearances of tumors, though of great interest, does not afford any reliable information as to the malignancy or otherwise of the tumor; possibly in the future, by great care in the employment of proper methods of fixation, our knowledge of the microscopic appearances of cells may become more extended.

Literature.—Out of a large number of works on medical microscopy which have recently appeared, the older standard works of Peyer, Friedländer (edited by Eberth), and Bizzozero still hold their place. Von Jaksch, "Klinische Diagnostik;" Klemperer, "Grundriss der Klinischen Diagnostik;" v. Kahlden, "Technik der Histologischen Untersuchungen," and Ranvier, "Technique d'Histologie," may be mentioned as among the best productions of the recent literature on the subject. Behrens, "Hilfstabellen für Mikroskopische Arbeiten," and the latest edition of the "Microtomist's Vade-Mecum," contain valuable recipes, embracing all the common formulæ. For details of the bacteriological methods, special works upon the subject should be consulted. On the subject of the blood, besides the imposing monograph of Hayem, which contains over one thousand pages, shorter monographs have been written by Graeber and von Limbeck. The publications of Erlich, especially the collection of reprints entitled "Farben-analitische Untersuchungen zur Histologie und Klinik des Blutes," presents, in a compact form, a good deal of information upon its author's peculiar methods, which was formerly very widely scattered. Unfortunately this work is not yet completed. Most of the important literature upon medical microscopy, however, still lies scattered through the medical and microscopical periodical literature.

Wyatt Johnston.

MILITARY HYGIENE. The principles of military hygiene have undergone no change during the last six years, but there have been some modifications of its application to United States troops which deserve notice here and consideration by those who may be intrusted with the care of State troops and of armies yet to be raised. Some points omitted in the original paper may also be stated.

Clothing.—*Duck.*—The issue of white cotton-duck sack-coats, trousers, and overalls is now authorized as uniform in extreme Southern latitudes in summer, at the discretion of department commanders. The anticipated theoretical objections to the use of cotton do not seem to have been realized, and the increased comfort to the men by the relief from the oppressive woollen is a sanitary advantage. But light mixed woollen and cotton underwear should accompany cotton uniform. The effort to have authorized a dust-colored uniform, one-third wool and two-thirds cotton, should be encouraged for those regions where long-continued high temperature enervates.

Collars.—Among the disadvantages of tight collars, sometimes worn in uniform, is the very serious military one of affecting the vision through disturbance of the cerebral circulation. This is not apt to occur frequently, but it should be guarded against as a possibility.

Leggings of brown canvas duck, to be worn on the march or in campaign, are now required for all foot troops. Their utility in a prolonged campaign is yet unproved. The disadvantages are those of extra pieces of clothing to be looked after, a slightly additional weight, and, particularly, difficulty of adjustment, especially when most required, in wet and mud. When tight enough to remain in place, they are liable to be too tight and to cause the feet and ankles to swell. Cotton and light canvas wrinkle into bands, and light leather becomes harsh after wetting.

Boots.—All mounted troops spend more time on foot than in the saddle, and in this country cavalry will doubtless, as heretofore, continue to fight much dismounted—to be veritable dragoons. The cavalry boot is only suitable for the horseman when mounted, for it is apt to chafe in walking. The comfort and efficiency of the cavalry would be increased by substituting for the boot a shoe, with a heavy detachable leg and stiff brace, to be worn only when mounted.

Barrack Shoes.—Shoes with canvas uppers are now issued for barrack use. They are much lighter and more comfortable for this purpose than the marching shoe.

Carriage of Weights.—As set forth in Vol. III., the transportation upon his person of the clothing and accessories necessary for the independence of the modern soldier in the field has only been accomplished with great personal discomfort and fatigue, and by the expenditure of so much vital force as seriously diminishes his effective strength. An equipment devised by Colonel Merriam, Seventh Infantry, practically solves the problem. By it rations, underclothing, extra ammunition, and blanket can be conveniently carried by one piece of equipage, without constriction of the chest or of the arm-pits. The weight is supported by the hips, with some assistance from the collar-bones, and there is practically no pressure upon the back, and absolutely none upon the breast. Numerous actual trials have demonstrated its efficiency, and there can be no question as to the practical value of this device, and its great superiority over the official blanket-bag. But it has not yet been formally adopted, and experimental issues continue to be made.

A very recent device of Lieutenant Dodge, Twenty-fourth Infantry, to support the blanket-roll, havresack, and canteen, is a flexible wooden strip to which the roll is lashed. It passes over the shoulder and rests against the opposite side, as the blanket would. The presumed advantage of this wooden support or yoke is that it very slightly interferes with motion, and that its elasticity takes all pressure from the chest and back. Where the curve passes over the collar-bone, a leather strap, like that used on a crutch-head, takes off the rigid bearing. How far it will comply with the conditions of active service is yet undetermined. Trial samples are to be issued.

Food.—The unwritten custom of the service that served three meals a day in garrison, is now formally recognized in the regulations. The Quartermaster's Department now supplies certain cooking utensils and table furniture, thus relieving for food money formerly diverted from the company fund. A greater improvement has been the abolition of the post fund (Vol. III., p. 755), and the direct division of the profits of the bakery between the various companies, in proportion to the number of flour rations turned into the bakery by each. This releases the ration from an indirect tax for articles other than food.

Bread.—The standard ration of bread remains at eighteen ounces, where fresh vegetables can readily be obtained. But it may be increased to twenty-two ounces by post commanders, on the recommendation of councils of administration.

Fresh Vegetables.—A recent law adds one pound of vegetables to the ration, an allowance ample for all sanitary requirements. This may be issued as 100 per cent. fresh potatoes; or, 80 per cent. fresh potatoes and 20 per cent. fresh onions; or, 70 per cent. fresh potatoes and 30 per cent. canned tomatoes or other vegetables. No savings from these are purchased by the Subsistence Department. Partly on account of their bulk, and partly from their perishable nature, there will be great difficulty

in the actual issue in campaign or under adverse climatic conditions; that is to say, just when most needed will be the greatest risk of failure. But the recognition of their importance and the attempt to supply them constitute a sanitary advance. In receiving canned tomatoes it is to be remembered that the contents of the so-called two- and three-pound cans fall short of their nominal weight.

Vegetables shrink about ten per cent. in cooking, exclusive of waste.

Cheese.—Cheese is no longer supplied as an alternative part of the travel ration. It is, nevertheless, recommended as an occasional addition by purchase to the mess table.

Beef.—The beef ration is estimated as the raw issue. There is a waste of 5 per cent. in cutting up the carcass, and a shrinkage of about 25 per cent. in cooking. Beef should be killed twenty-four to thirty-six hours before issue in temperate, and eight to ten hours in hot climates.

Bad and Diseased Meat.—Decomposing meat should not be eaten, although some abnormal palates and educated digestive organs regard it as a delicacy. Diseased animals ordinarily should be condemned as food, but such emergency issues may be made in the prolonged absence of other meat. Cattle dead of the rinderpest and horses dead of glanders have repeatedly been eaten with impunity. But it is essential that such meat be thoroughly cooked, and it is much safer that all the blood be drained. Tuberculous meat and milk may affect the consumer; but it is probable that actinomycosis, a less communicable disease, is often mistaken for the former. Animals with malignant pustule are always dangerous, and their carcasses should be burned, not buried. Beef and pork may communicate tape-worm, and pork, trichina, when imperfectly cooked. Thorough cooking of all doubtful meat is very necessary. Sausages and meat-pies sometimes become toxic from the development of a substance not yet isolated; and hash prepared over night in warm weather, and stale mixed dishes, are liable to induce intestinal disorders.

Baking and Cooking.—*To Bake Bread.*—In the field, portable ovens will probably be used for large commands, but baking will generally be done by company cooks for brigades or less. Flour grown on soil deficient in lime may make bread that, after rising well, becomes heavy and sour on cooling. The use of strong lime-water in making-up such dough corrects this defect. Of the various methods of baking in the field, the simplest is to fill a small hole in the ground with a wood fire, and when this has thoroughly burned out to place therein, on a stone, a mixture of flour, salt, and water, covered with a tin plate and surrounded by hot ashes. Unless the heat is kept below 212° F. the bread will be tough. Or, two mess-pans may be taken and the rim of one be cut down all round, so as to leave a jagged border. Fill the cut pan two-thirds with dough, and invert over it the perfect pan. Place both in a hole eighteen inches deep, where a wood fire has burned several hours and from which all the embers except two or three inches have been removed. Cover them with hot ashes and with earth, and leave them five or six hours. The rough edges of the cut-pan allow the gases to escape.

To Cook Meat.—For boiling, the piece should be as large as possible and be plunged in boiling water, to remain five or ten minutes. This coagulates the albumin in the outer layers and thus retains the inner juices. As at above 170° F. the meat would become hard and indigestible, the temperature of the water should be reduced to 160° F., and the meat should remain in it fifteen minutes for every pound of its own weight. Baking, which is not roasting, as it is ordinarily called, is treating meat exactly similarly to boiling, and for the same reasons, except that a dry heat is used. In frying, so called, the slowly heated fat exudes acids, generally injurious, that envelop the particles of meat with an indigestible coating. Stewing, properly conducted, is admirable. Small pieces of meat should be kept for about two hours in a little water at not far from 134° F. This partly extracts the juices, keeps the albumin semifluid, and enriches the accompanying liquid which must be served with the meat. Stewing is the exact opposite of boiling or baking, both in theory and practice. For cooking or baking in the field, the Buzzacott field-oven is well adapted for company use.

Habitation Sites.—Soils to be avoided are those that hold moisture. Granite and the metamorphic rocks are usually healthy. So are clay slates, but drinking-water will be scarce. Deep gravels, unless dominated by adjacent ground, are always healthy; and gravel hillocks are the best of all sites. Sand, when pure and deep, is healthy, but such a site soon becomes charged with refuse, which passes through it laterally as well as perpendicularly. Water is sometimes held by clay under dry sand and becomes hurtful. Clay and alluvium are generally suspicious from the contained moisture, but well-cultivated soils, rice-fields excepted, are desirable.

Topographical Sites.—Enclosed valleys, ravines, or the months of ravines, any ill-drained grounds, the neighborhood and especially the lee of marshes, the northern side of mountains or high hills, and in warm latitudes the northern banks of rivers, are to be avoided.

Vegetation in Relation to Sites.—Close-lying grass, kept well trimmed, is always healthy. Rank vegetation should be cut in the heat of the day and be burned before decay; but the soil should not be disturbed, nor heavy brush near a marsh. Belts of trees and tall shrubs are a barrier against malaria, but decaying vegetation is harmful. The eucalyptus by its evaporating power antagonizes the production of malaria in frostless climates, and the sunflower guards against it in others. Trees break cold winds in cold climates, and cool the ground in hot climates; they are hurtful only when they cut off the light and air from a domicile, making it dark and damp.

Quarters.—Ordinary houses when used as quarters may be estimated to accommodate, in rooms fifteen feet wide, one man to the yard in length; in those between fifteen and twenty-five feet in width, two men; in those more than twenty-five feet wide, three to the linear yard.

Marches.—The latest drill regulations abandon "common" time, and require the "double" step to be 36 inches instead of 35 inches. Unless otherwise directed, all movements are in "quick" time, at the rate of 120 steps, 30 inches in length, a minute.

Water-Supply for Military Purposes.—In the field, on halting for camp, the water-supply should be immediately protected against waste, against pollution, and against the turbidity that follows trampling the margin into mud. The less the supply the greater the care, and an officer should be in charge when the quantity of water is disproportionately small. In the case of a small spring the supply will be increased by digging it out and sinking a barrel or other casing. In a shallow stream immediately create a small reservoir for drinking by a temporary dam, with one lower down for the horses and one still lower for washing. When the camp is permanent and the supply relatively small, preserve the water that flows by night in reservoirs, conduct the overflow into a succession of half-barrels, all connected by little gutters to avoid waste, for the horses, and detain the surplus in a still lower reservoir. Horses drink better and more rapidly when the water is five or six inches deep, each horse taking about a gallon and a half at a time and requiring three minutes for drinking. If allowed all they will drink they consume six to eight gallons a day, according to season and work, and about three gallons a head is needed for grooming and police. On the march a man requires for drinking and cooking six to eight pints a day, according to climate, and an equal amount for washing the person. In barracks the allowance should be ten gallons a head for all purposes except water-closets and baths; with these, twenty-five gallons. The foregoing are minima figures, requiring to be increased in hospitals by several times as much, depending on the character of the cases.

Ice.—The sources of domestic ice-supply for military posts, as for other settlements, should be carefully se-

lected and guarded; for water by no means parts with all its impurities in freezing.

For the special discussion of sewers and the disposal of waste water-supply, disinfection, the avoidance of disease in permanent posts, and similar subjects that affect civil as well as military life, reference must be made to the papers devoted to them. But it is always to be borne in mind, and to be impressed upon commanding and other officers, that deodorants are not necessarily disinfectants, or that to replace one bad smell by another rarely antagonizes the poison that may sap health. Especially are those in control to be taught that polluted water is practically without remedy—that the only safety is in keeping the water-supply inviolate.

Alfred A. Woodhull.

MILITARY NURSING.—In military practice the nursing of the sick is placed in the hands of privates of the hospital corps. These soldiers are either transferred to the hospital corps after one year's service in the line, or they may be enlisted from civil life and instructed for a short period in one of the two schools of the hospital corps before being sent to the various army hospitals for duty. By these methods there is secured for nurses a body of men who have been disciplined by a military training, and who are thus supposed to be fully alive to the necessity of subordination to authority and implicit obedience to orders.

These soldiers when received into the hospital corps are entirely ignorant of the duties of a nurse, and they must be instructed by lectures, demonstrations, and actual experience in the ward. This combination of military instruction and training school for nurses results in methods of nursing somewhat different from those found in civil life. In the theoretical rules for nurses in time of peace there can be no difference in civil and military practices, but it is more in the details that changes arise. Many of these changes are due to the peculiarities of military life, as, for instance, the necessity of having the nurses under complete control in case of active service in war, or in time of epidemics. In such times service must be compulsory, for it is not practicable to depend on nurses volunteering in the cause of humanity, as would be the case in civil life. This article will not deal therefore with things common to the two, but will be confined to pointing out the differences, where such may be supposed to exist. The matters to be discussed will be presented under the following headings: 1, The Nurses; 2, The Management of the Ward; 3, The Management of the Patient; 4, Nursing in the Field.

1. The Nurses.

Qualifications.—Before a man can be transferred to the hospital corps he must have the following qualifications: He must have served at least one year in the line, must desire the transfer, must be unmarried, under forty years of age unless he is a good cook or nurse, must be in good physical condition, of good habits, and possess a good character; be able to read and write, have good general intelligence, and an aptitude for his duties, and must give assurance that he intends to serve out his full five years of service, and not seek his discharge beforehand, in any of the numerous ways now available.

The pay of the private of the hospital corps is eighteen dollars per month, which is five dollars higher than that of a private in the line, and his money allowance of clothing is that of a corporal. This inducement of slightly increased pay and allowances should be the means of getting a very good class of nurses, particularly as the above restrictions are thrown around the matter of transfer in order to exclude undesirable men. The constant instruction that these men receive is slowly but surely building up a good class of nurses, notwithstanding the frequent changes by discharge and re-enlistment. Should all the plans in this direction prove successful, the United States soldier, when sick, should receive the constant supervision of trained nurses whose efficiency should be excelled by none in civil life.

The military nurse is a soldier, and as such is subject to all the rigid discipline of military life. This has its advantages as well as its decided disadvantages. Such discipline enables the surgeon to exact the most punctilious attention to the details of nursing and the execution of orders, under penalty of court-martial for neglects and disobediences. Every physician knows how advantageous this is in certain critical cases where he is desirous of having his plans carried out to the letter. In such cases where the faithfulness of the attendants is not above suspicion, the physician's anxiety is far greater than it should be. If the nurse can be depended upon, there is no doubt that lives are often saved where it is a matter of good nursing.

There is a bad side to the discipline which exacts an implicit obedience to orders. The private soldier is usually under someone's orders, and has all his thinking done for him. This course of life undoubtedly weakens his independence of thought and action in emergencies. He is too apt to be on the lookout for orders, and unless some are forthcoming he may be entirely at sea. Modern methods of military instruction are trying to overcome this by teaching each soldier his individual importance in battle. On the same plan, the instruction in nursing aims partly to undo the results of the discipline that turned the man into a machine. The nurse is taught to observe his patients closely, watch for unfavorable signs, think for himself, make frequent reports to superiors, and to prepare the way for changes of treatment his teaching tells him have been made necessary by the change of symptoms.

In civil hospitals when a nurse proves himself to be unfitted for his duties by reason of inappropriate temperament, viciousness, or incorrigible stupidity, he can be unceremoniously discharged, but not so in military life. Courts-martial are extremely conservative, fight shy of all innovations, and not being composed of medical officers they are difficult to convince in the matter of the offences of nurses. The disadvantage of military custom in this respect cannot be avoided and must be tolerated. Thus it happens that not infrequently improper nurses are retained when their absence from the hospital would be more desirable than their presence in it.

The military nurse has the same kinds of difficult, fatiguing, and disagreeable duties as in civil hospitals, and must possess the necessary qualifications of good health, patience, forbearance, kindness, and great self-control. Truthfulness, honesty, habits of punctuality and order, and the ability to work according to a system and not hap-hazard, are also important, as well as the ability to keep secret his confidential knowledge of the patient's private affairs. Many of these qualifications are brought out and strengthened, if not generated, by the military training which every military nurse receives before his transfer to the hospital corps.

Not every man has the temperament necessary for a good military nurse. Nervous and excitable men are entirely unfitted for such work in any hospital, either civil or military, because they worry and excite the patients by their manner, and they may do irreparable mischief. The sanguine, hopeful man is unfitted for military nursing because he is too apt to be depressed by misfortunes, rebuffs, thoughtless and unjust reprimands from immediate superiors, and the thousand and one annoyances inseparable from military life. He so loses heart under adversity that he will neglect highly important duties while suffering from these annoyances. The man of phlegmatic tendency, whose sensibilities are not too acute, and who is hard to excite, comes nearer to the ideal nurse than the others. He is not especially annoyed by the most exasperating circumstances, and is cool and collected in times of excitement.

In military practice the surgeon is often unable to obtain professional assistance of other surgeons. It is absolutely necessary for him to have skilled assistants in operations that are not only exceedingly difficult, but made far worse by the adverse surroundings of military life. The nurse must be relied upon, and for this reason the lectures and other instruction to the hospital

corps must go much further into the details of the theory and practice of medicine and surgery than is usually deemed necessary to qualify nurses for work in civil life.

Though military custom steps in to prevent any marked confidences between surgeons and nurses, and though there is an official barrier between the two that cannot be broken down, yet it is true that the surgeon must be brought much closer in contact with the men under his orders than is the case in the line. This close relationship comes from the necessity of the surgeon receiving from the nurse confidential reports of the patients, their actions, symptoms, and conversation. Soldiers are very apt to malinger for the purpose of escaping duty or of obtaining discharge from the service and subsequent pension. Of course they will hide everything they can from the surgeon; but the nurse, from his intimate association with the patients, learns the true state of affairs, and is often depended upon for true reports. The surgeon must know the truth in these matters, for upon his report depends in great part the action taken in each case, as to compelling the malingerer to do his full duty. In other cases false reports may have been the cause of such action on the surgeon's part as will result in great injustice to a worthy soldier. It will be impossible for the surgeon to be informed, unless he can induce the nurse to feel that there is a confidential relation between them that is necessary for the proper performance of duty. The nurse must therefore be sufficiently intelligent to be able to hold such relations without detriment to himself, the surgeon, or the United States service.

From all that has been said it can easily be understood why so much is expected from a military nurse, and why such great efforts are made to obtain a desirable class of men. The pay and allowances, including board, clothing, lodging, free medical attendance and medicines, are the equivalent of about $55 to $60 per month to a city laborer in civil life. This is not small pay when it is considered that the Government has taught the man his trade whereby he earns this amount. Nevertheless the actual money allowance, $18, is not great enough to attract that high class of men which the foregoing shows would be the ideal army nurse.

Duties.—The nurse in charge of the ward of a military hospital in peace times has numerous duties to perform, some of which are purely military, while others are police duties requiring him to keep the ward and everything connected with it in a cleanly and orderly condition. These duties are exactly the same as those of soldiers of the line as far as the barracks are concerned, and the nurse is supposed to go about these duties without special instruction. Beyond his military duties as a soldier, and his combined duties as a room orderly and in charge of the ward, there are his more important duties relating to his care and treatment of the patients. These duties as a nurse are the most responsible, and therefore the most important ones he has to perform while on hospital duty. In the field, and occasionally in the hospital, he may have the important duty of rendering first aid to the sick and wounded in emergencies during the absence of steward or surgeon. The necessity of having efficient men who can perform these two duties of nursing and giving first aid, is one of the most important reasons for the establishment of the hospital corps. It is just as important for the wounded soldier to be attended by trained nurses as it is for wounded civilians, and the army, in this respect, is following directly in the path of civilian practitioners, who have long ago found out the necessity of having elaborate training schools for the special instruction of nurses.

Instruction.—A system for the higher theoretical instruction of army nurses has not yet been completed, as sufficient time has not yet elapsed to see how much can be done in the short period of service. The nurses are apt to leave the service at expiration of the period of enlistment and not return. If two or even three years of constant instruction are requisite to make a thoroughly competent trained nurse, it is evident that as soon as the army nurse becomes proficient his services are lost. Nevertheless much good work can be done, and there is no reason why the military nurses should not in time become as proficient as any others.

The instruction is by lectures on elementary anatomy, physiology, the rules of hygiene, and such knowledge of medicine and surgery as will enable the nurse to perform efficient emergency or first aid service. Then there are series of lectures on such topics as the observation of symptoms, thermometry, temperature charts, pulse, administration of medicines, counter-irritants, disinfectants, preparations for surgical operations, the giving of anæsthetics, instructions in special diseases, and indeed the large number of topics usually found in the manuals for the theoretical instruction of nurses. In times of peace it is not possible to give nurses the varied practical experience that is desirable, but it is found that they learn quickly and remember fairly well the methods used in each case attended. Every opportunity is seized to impress upon them any practical points in nursing each case, and many medical and surgical cases serve as material for clinical instruction to the whole detachment of the hospital corps present.

The military nurse is not expected to be expert in methods of massage, of giving inunctions, fumigations, electrical applications, baths, and kindred special subjects, although they may be included in a general way in the system of instruction. The cases requiring such special treatment are too rare to give sufficient practical experience. When a case does occur, special instructions must be given to the nurse in charge of the case.

He is taught the importance of his duties by explanations of cases in which it is not so much the medical treatment as it is the careful attention to the patient's wants, and efficient nursing, that carries the patient through his illness. It is also sought to impress on him the high professional attainments he is expected to acquire, if he is to be depended on to assist the surgeon in different operations in certain circumstances already mentioned.

There is a threadbare proverb, which is repeated with nauseating frequency by military men, "In times of peace prepare for war," and to no one is this any more applicable than to the military nurse. In peace he has ordinary routine cases, with but little to do, but he may be aroused from this with startling suddenness. An Indian war may arise, and he find himself loaded with work, with far more patients to look after than he ever imagined, and it is necessary, therefore, to have his work so well systematized that he can do the greatest good to his sick and wounded charges. The system that is aimed at in the above instruction should be so designed as to be applicable to the sudden emergencies when each hospital is loaded down with wounded.

Women are more careful and tender in their attentions to the sick, and on that account are said to make better nurses than men. On account of woman's instinctive tact, which is the knowledge of what to do for the sick and how to do it, there is not so much written or said on this part of the subject of nursing as might be. It is all left to her instincts. Now, female nurses cannot be obtained for army hospitals, and indeed in small hospitals where all kinds of cases are put in one ward, the presence of women would be undesirable, and perhaps quite indelicate. The army nurses must, therefore, be men, and not being possessed of those instincts of gentleness and sympathy with sufferers that go so far to make the sick well, or rather hasten their recovery, they must try to make up for their deficiencies by careful attention to all the little details of nursing that come so naturally to women, and which, taken all together, go to make up what is called a good nurse. In times of war, where large numbers of sick and wounded are collected into immense hospitals, there can be a separation of cases, and in the majority of wards women can be admitted to perform all those necessary attentions to the sick, leaving the male nurses in charge of the wards free to devote their time and energies to the general management of the cases and the performance of those duties that the women cannot do. In times of peace and in small hospitals the privates of the hospital corps must

learn to do all. The instruction of the army nurse must therefore include such matters, pointing out as well as a man can, the humane thoughts and feelings which prompt women to do those things which are so grateful to the sick.

In peace or war the army hospitals do not fall into that serious error sometimes seen in civil hospitals, of placing women nurses in complete charge of men's surgical wards. This error comes from the natural swing of the pendulum of public opinion, for when the training of women nurses became popularized, nothing would do but that the women should take full charge, even of cases that their modesty and sense of decency forbid them to touch, which they could not attend to, and which were therefore neglected, often to the serious detriment of the patient. Men must be in charge of men's wards, let the women assistants be around as thick as bees if they want to. To depend on refined women to uncover men and inspect dressing of the groin for instance, to see that everything is undisturbed, is entirely out of the question.

Personal Appearance.—A nurse should always be neat and clean in appearance. It would seem unnecessary to call a soldier's attention to this fact, yet it is unfortunately true that occasionally a nurse has to be warned that his personal appearance is enough to make a well man sick, and a sick man worse. If the nurse is clean and neat he certainly has an effect for good upon the patients he attends. If his hands are dirty, and his clothing dirty or disorderly, and in this condition he hands patients their food, or in bad cases feeds them, they are apt to be nauseated by the presence of so much dirt near their food, and thus recovery may be interfered with.

In hospitals where there are many patients in one ward, one nurse cannot do all the work, and therefore scrubbers and helpers do all the cleaning up and the heavy work generally, leaving the nurses who come closest in contact with the patients freer to keep themselves as clean as possible. In small military hospitals the nurse in charge of the ward must do all the work, and he must, therefore, exert special care to keep himself clean. After doing any work that would soil his hands, he should hasten to clean them, even if he do this dozens of times each day. By carefully arranging his work a nurse may manage to do at one time most of his dirty work of cleaning up the ward, and thus save himself much unnecessary trouble. In such small hospitals where one man does all the work of a ward, it is found by experience that his hands and finger-nails are not in the condition that makes perfectly aseptic surgery possible, if he is to handle instruments and dressings. This state of affairs gives considerable worry to the surgeon who is compelled to exert himself to avoid even the slightest possibility of wound infection, and he is further compelled to attend to many details which in civil hospitals are looked after by the nurses.

The habits of cleanliness which are instilled into soldiers as a duty come to the nurses' aid as far as personal cleanliness is concerned, and make it easier for them to comprehend the instructions as to the precautions to be observed to prevent infecting themselves or other patients. Nurses are taught to keep and use a tooth-brush, and keep the mouth in as clean a condition as possible. Beards are not worn, as they certainly increase the dangers of infection.

As a means of furthering personal cleanliness and neatness, nothing is better than a white jacket, with or without a white apron extending from the waist to the knees. These always look neat, and as soon as soiled can be cleaned. When clothed in them the nurse is carrying around with him a far less number of disease-germs than if he has on his military blouse that he has been wearing in the ward for several months. A dirty old blouse is a danger in any ward, and it would be far better for each nurse to have white clothing that can be washed as soon as soiled.

Care of Nurse's Health.—Everyone knows that a strong healthy man is far less liable to contract diseases than one who is weak and run down in health from any cause. It is therefore important for nurses to keep themselves in as perfect a condition of health as possible. Particular care is necessary in the case of nurses who in times of epidemics are apt to be closely confined and much overworked. People who are called upon to nurse near relatives who are prostrated by illness usually make a very great mistake by supposing that they are doing the greatest good by giving unremitting attention to the patient's condition and none to their own. They usually break down, and then there are two patients to be taken care of instead of one. The nurse can do the greatest good to his patients by attending to his own health. In a general way it may be said that he should avoid all excesses, either of eating, drinking, exercise, or anything else; he should cultivate the most regular hours and try to get a half hour or hour's exercise in the fresh air every day. The last direction is of great importance, for although the ventilation of wards is made as complete as possible, it can never be made perfect, and the inmates are sure to breathe air that is impure to at least a slight extent.

A drunken spree so lowers a man's vitality that he is extremely liable to contract the diseases with which he comes in contact. This lowered vitality and the exposure to cold during the drunkenness fully explain the great prevalence of pneumonia among drunkards, and its mortality. From a medical standpoint it cannot be said that a very small amount of alcohol does any particular harm to a man in ordinary employment, but for a nurse, whose health should be perfect without any stimulants, it can be truly said that a small amount, usually called "moderate drinking," is very apt to do him harm, and on the score of his health alone he should be a total abstainer. If he attends cases of a contagious disease, his total abstinence may be his salvation by aiding him to escape infection. Of course this refers to his conduct when off duty. When on duty, even the slightest drinking can never be tolerated. But on or off duty there are various other reasons that make it impossible to tolerate drinking in a nurse. If but slightly under the influence of liquor he is too dangerous to have near the sick, for he is liable to make very serious mistakes. If he is addicted to drink, no liquors can be placed in his care, and he is useless from this point alone. It is therefore a rule in civil or military hospitals to discharge as soon as possible any nurse who is found to have been drinking while on duty. If he gets drunk while off duty, he is too undesirable to be re-enlisted.

Sleeping Rooms.—In civil hospitals it is a recognized principle that the nurse should not be compelled to spend all his time in the sick-room. He must have hours out of doors, and, most of all, he must have an entirely separate sleeping apartment. Perfect health is supposed to be incompatible with any other arrangements. Upon this principle it is now the rule to have in military hospitals a dormitory or barrack-room to be used by the members of the hospital corps. The small number of patients that require attention at night does not necessitate the detailing of a night nurse. Consequently it has become the usual custom for the day nurse to sleep in the ward, an objectionable custom that can scarcely be obviated with the present arrangements.

2. Management of the Ward.

Quiet.—One of the strictest rules for the management of a ward is that referring to quietness and order. No boisterous conduct, loud talking, or disorder of any kind is allowed under any circumstances. This is essential for sick men, who usually require perfect quiet and rest. Now the first step toward accomplishing this must be taken by the nurse. He should never talk in a loud tone of voice, nor should he be noisy in any of his actions. One of the rules in training-schools for nurses is that forbidding the use of starch in their clothing, in order that they may move around quietly without making a noise that would disturb the patients. Another rule governs the kind of shoes, which must be of such soft material that squeaking noises will not be heard. Now male nurses should remember these two rules, although that

referring to starch in the clothing is not applicable to them. As far as the shoes are concerned, there should be no trouble in military hospitals, where slippers are supplied for the purpose. When on duty the nurse should use the regulation leather slippers. These permit him to move around at his work without the least noise or disturbance that could annoy the most irritable patient he may have. In everything he does, whether cleaning up the ward, sweeping, moving bunks, administering medicines, or giving directions to patients, he should keep constantly in mind the utmost necessity for order, quiet, and the general peacefulness of the ward.

Visits of Friends.—When people are very sick they are excessively annoyed by the visits of friends, who are well meaning and make their visits under the impression that they are doing good. If the surgeon orders that no one is to be admitted to the sick-room, the nurse understands that such an order is given to protect the patient's life, and that the order must be carried out to the letter. Should an intruder force his way into the ward, and by his presence endanger the lives of patients, by making them worse, he should be ejected by force, if he does not leave when ordered. The nurse is there to protect his patients and preserve absolute quiet and order, and he must do it if he has to exert force. Of course this responsibility is great, and he must never think of using force until he has exhausted other means, and even then he must think whether or not the disturbance would be increased by any forcible means used to stop it. In all cases where it is practicable he should not depend on his own judgment but report the matter without delay. During convalescence the visits of friends may be looked at in an entirely different light. At this time a short visit may be very acceptable, as it introduces a pleasant change into a monotonous life, providing the visitor is an agreeable friend. Should the patient's condition be made worse by such visits, the surgeon will at once forbid repetition of them for some time.

The situation and surroundings of large civil hospitals make it difficult, if not impossible, for intruders to enter the wards and produce disorder; it is different at military posts where the small hospital may be entered by visiting soldiers. The military nurse therefore has to look after the matter of visits of friends of patients, and must have definite instructions.

In small army hospitals it is impracticable to have regular visitors' days as is the case in large civil hospitals.

Visits of Clergymen.—The visits of clergymen to the sick come under a slightly different rule, as they are privileged visits. As a usual thing the consolation they offer to the sick is decidedly quieting and soothing in its effects, providing, of course, that the patient understands the visit is made merely to help him bear his trials. On the other hand, if the patient imagines that he is in danger of death, the visit of a clergyman may confirm his worst fears and have a depressing effect. It is only in very rare cases, that are chiefly nervous, that the clergyman is excluded along with everyone else. This whole subject is so exclusively under the control of the surgeon that it may be said to be entirely beyond the sphere of the nurse's duties, except that report should be made if anything goes wrong. As the army chaplain is required by custom and regulations to visit the hospital, the visits are encouraged, and the nurse, no matter what his individual religious opinions are, should make it his duty to show every courtesy possible to all clergymen, and assist in making their visits as profitable as possible.

Inspection of Ward.—A hospital ward must be ready for inspection at all times, but as it is a rule in military hospitals to have a rigid inspection of the whole hospital in the morning, the greatest cleaning is done right after breakfast. This morning inspection should never be made the excuse for allowing a ward to get dirty or disorderly at other times. A nurse should so fully appreciate the importance of his work, and attend to it so well, that there never should be any necessity for an inspection.

Temperature of the Air.—The nurse is absolutely responsible for keeping the proper temperature of the room. What this temperature is depends upon circumstances. In windy, cold climates, it may be necessary to keep the temperature up to 75° or even 80° F., but in places where it is calm a lower temperature, 65° or 70° F., may be allowable even in winter. Rooms full of colored soldiers must be kept warmer than others, for the negro seems to require a higher degree of heat for comfort than a white man. Whether or not this higher temperature is proper cannot now be discussed, but as the sick man must be made comfortable as the first step toward recovery, it is allowable to have the room temperature slightly higher to suit the negro. This permission must not be imposed upon and made the excuse for carelessly or deliberately allowing the temperature of a room to rise to such an improper height as 90° to 95° F., as it has sometimes been found.

The nurse must carefully study in his ward the arrangements made for regulating the temperatures. There may be heating by means of hot water or steam from radiators in the room. There may be hot-air registers, the air being warmed outside the ward by coming in contact with pipes of hot water or steam, or the hot surfaces of furnaces. In all frontier hospitals there are stoves. Whatever method is used, the nurse should thoroughly understand it, and if there are parts beyond his knowledge he should ask for information without delay. If the room gets too hot or too cold, he should, by the simple turning of a valve, register, or draught, be able to remedy the defect.

Ventilation.—The ventilation of the ward is just as important as the heating. A nurse who does not know how to ventilate his ward and keep the air pure is not efficient. It is not necessary for him to understand and be able to explain all the different systems of ventilation that are in use in hospital wards, but by all means he should perfectly understand the particular system in the ward he has charge of. If there is any part of the system he does not understand he should inquire of steward or surgeon, and have thoroughly explained the whole apparatus, with its shafts, valves, registers, flues, the reason for the present positions, and the methods of stopping, increasing, or decreasing the flow of air.

Care must be taken that the apparatus is not interfered with by patients. Soldiers, whether in ward or barracks, will always shut up every opening in cold weather unless they are looked after. Indeed, in some barracks the ventilators are found closed at every inspection. These are closed on account of cold draughts or a low temperature of the room. In the latter case the fires must be looked after, and if it is found that the stoves will not keep the ward warm without closing ventilators, the matter should be reported to the surgeon for his action.

The construction of many army hospitals on the frontier, and their small size, make it somewhat difficult to manage the ventilating apparatus. In very cold weather—thirty to forty degrees below zero—no ventilating system yet applied is efficient. In the wooden temporary structures much more air can come in through the cracks in the walls than one would suppose, particularly in places exposed to the wind. The defects of the ventilating apparatus are balanced by the defects of the building. Many a nurse may have served a long time and never have noticed any necessity for looking after the ventilation.

The nurse is expected to follow the practical rule of noticing, every time he enters the ward from out-doors, whether or not there is a perceptible odor. If there is, some change in the ventilation is necessary. Cold draughts are to be avoided as specially dangerous for the sick.

Plumbing.—There should be, and usually are, no plumbing arrangements in the ward, except, perhaps, the pipes carrying gas when that is used for lights. All water-pipes, drains, urinals, wash-stands, and other plumbing arrangements are placed in adjoining rooms, separated from the ward by closed passage-ways. Yet these rooms are usually under the direct care of the nurse, and it is his duty to become familiar with them at

once. It is an easy matter to follow up the pipes and find their uses. In the case of traps in the soil-pipes and drains he should know how they work, how they are cleaned out, and how accidents to them are to be remedied. A little care to these appliances saves many accidents, much inconvenience, and great expense for repairs. The least appearance of foul odors from the drainage system, or anywhere else for that matter, must be reported without delay. It is rare, indeed, to find plumbing arrangements so complicated that an intelligent nurse cannot understand their uses and methods of working if he spends a little time and thought on the subject.

Amount of Light.—There is but little attention paid to the amount of light in the sick-room, although the subject is quite important and comes directly within the sphere of the nurse's duties. Formerly the sick in a private house were placed in a dark and ill-ventilated room, under the impression that it was quieter and better. There seemed to be an idea that if it was quiet at night, somehow or other it was the darkness that caused the quiet, and that therefore the darker the sick-room was kept, the better it would be for the patient. As this idea has been exploded for a long time, we find the new ideas reflected in the army hospitals, which are built with a profusion of windows, so that there are no dark places, and light enters on all sides.

This throws new duties on the nurse, who has a few points to attend to in regard to the lightness of the ward. While we have shown that darkness is to be avoided, this should not lead to the opposite extreme of making the room too brilliant. *Dazzling light* is painful to all sick men, and in certain nervous cases, too much light may make them worse. It is, for instance, very wrong to allow the sun to shine in the patient's face, or to turn his bed so that he looks directly at a brilliant white sky. The light must be evenly distributed and not brilliant at only one place. If the day is dark, cloudy, or rainy, all shades are rolled up and shutters opened. If it is hot, and the sun is shining brilliantly, the shades are all drawn down completely on the light side of the room. Those peculiar days when there are very bright white clouds in the sky are particularly trying to the eyes, and the shades must be drawn down for protection.

In the early evening only sufficient lights are kept to give a fairly good light to read by. When patients are very ill and it is deemed necessary to darken the ward in the early evening to favor sleep, the patients who wish to read must go to the reading-room, or, if confined to bed, postpone their reading until the next day. On hot summer afternoons it is quite agreeable to all sick men to have the room darkened for a short time so that they can have a nap—a habit that most old soldiers acquire. At night a dim light is kept burning so as to permit of walking around. A hand lamp is usually kept burning for this purpose, and if patients require attention it can be carried where more light is needed.

Army hospitals cannot be fitted up with a sun-room where convalescents can be exposed to the direct rays of the sun. In the rare cases that require such a sun-bath, the nurse must arrange the matter at some convenient window.

Many of the instructions given to the army nurse in the matter of the light may appear to be trivial, but much attention should be given to this instruction, because large numbers of the present hospitals are quite unfavorably situated on hot, dry, sandy plains in the West, where the light is very trying to the eyes. Unless these points are emphasized the matter is liable to be neglected.

Cheerfulness of the Sick-room.—The army nurse can have little to do toward decorating a ward to improve its general tone as to cheerfulness. A ward is doleful enough under any circumstance, but in military hospitals, which are greatly affected by the rigidity and sternness of military life, the conditions as to cheerfulness are doubly bad. Nevertheless, the nurse should understand the good to be accomplished by making the room cheerful and bright, even though he is not able to carry out the plan in military hospitals. The decoration of sick rooms is carried to its greatest extent in those charitable hospitals devoted to children, who are usually and greatly influenced by their surroundings. These rooms are in certain cases little treasure-houses of such ornamentation as can be made with the little money that is usually available for the purpose. It has its effect in making the little ones almost as happy and contented as though they were well, and this is a great aid in treatment. As sick adults usually relapse into a kind of mental childhood, they are also greatly influenced for the better by cheerful surroundings.

Cheap prints tacked on the walls, little bits of decoration by ribbons or hangings, a small bunch of flowers here or there, and a tasty arrangement of the plain and meagre furniture, are all great aids to the general cheerfulness. The neatness and cleanliness of the bedside tables must be looked after as directly tending in the same direction. The table-covers are usually towels, and they get soiled quite soon and must be replaced. Little articles on the table must be kept in order and ready for immediate use. Indeed, all the directions as to cleanliness, order, and neatness of the ward, though given with the special view of aiding treatment, have an additional value as enhancing the cheerfulness of the ward.

A word or two must be said about *growing plants* and *cut flowers* in the sick-room. The subject has caused great discussion as to whether or not it is injurious to the sick. We know that during the daytime growing plants give out oxygen and absorb carbonic gas, just the opposite of what man does. This has been the ground for arguing that they should be kept in the sick-room to help purify the air. It is not generally known that the amount of oxygen given out by the plants that can be kept in the sick-room is so small that in a week it would probably not equal the amount brought in through one good fresh-air register in one hour. On the other hand, during the night-time growing plants often act in the opposite direction, *i.e.*, give out carbonic acid gas and absorb oxygen, and flowers do the same thing all the time. Here, too, the action is so small that it can be totally ignored in a properly ventilated room. When plants are present in too great number they keep out the light of windows and keep the air too moist, and are therefore objectionable, though there can be no reasonable objection to a very moderate number. As far as flowers are concerned, it can be said that an atmosphere heavily loaded with the odors of cut flowers is distinctly and decidedly depressing to sick people, and to well people also for that matter. A profusion of flowers must be excluded, therefore, under all circumstances. As with growing plants, a moderate amount of cut flowers that does not appreciably laden the atmosphere cannot be objected to when tastefully arranged in places around the room, but is distinctly advantageous as increasing cheerfulness and brightness. In time of peace the army nurse may not have any occasion to exercise any discretion in the matter of cut flowers, but in time of war, in the large general hospitals, a possible occasion might arise. Charitably disposed women make it their duty to keep the hospitals supplied with flowers, and there may be an inclination to carry the matter to extremes, especially in the case of wounded men whose achievements in battle have made them heroes. Special attention to one man by his friends may call for interference.

Army hospitals having large wards do not permit of much separation of the sick, who must therefore be protected from everything of a dismal or depressing nature. It is particularly horrifying to be compelled to witness the actions of dying men or the sufferings of one in great pain. Therefore all such cases should be carefully bidden from view by arranging bed-screens around the bunk. For the same reasons, should a patient die, his corpse should be removed to the dead-house within a few minutes, or as soon as it can be done decently and without giving the impression of undue and unseemly haste. No one has the least desire to remain in the same room with a corpse, let alone sleep there. When *surgical operations* are to be done in the ward, all other patients must, as far as possible, be removed to another room. It will

make them worse to be witnesses to anything of the sort. Of course this refers to serious operations, but such things as lancing a boil or dressing a wound are not particularly horrifying, and can be done in the view of the others. Nevertheless, it is a good rule to have the screens ready when anything of that nature is to be done, for this gives a grateful sense of privacy and seclusion to the patient operated on. To most men of a very sensitive organization any unnecessary exposure of their persons is very disagreeable, and the protection of screens is almost essential. It is just as wrong to give patients the least unnecessary mental pain as it is to give physical pain that can be avoided.

The necessity for cheerfulness, neatness, order, and beauty in all the surroundings of sick people is not only the guiding principle in regard to the interior of hospitals, but also of their exterior. Wherever it is practicable, hospitals are found situated in large, open places, that are filled with trees, growing plants, grass-plots, flower-beds, and symmetrical gravel-walks, and the whole kept in the cleanest and most orderly manner. A special gardener is employed for the purpose when possible, but in the small army hospital a member of the hospital corps must be depended on for this work, and a detail as gardener, to keep the hospital grounds clean and with at least a respectable attempt at flower-gardening, is directly within the sphere of his duties.

3. MANAGEMENT OF PATIENT.

On Admission.—The military discipline maintained in army hospitals necessitates some change of the rules for the nurse's management of the patients. On admission to hospital the patient is to be undressed and put to bed at once. His valuables, watch, money, etc., are to be given to the steward to be placed in the office safe. His clothing is to be locked up in the closet supplied for the purpose, and under no circumstances should clothing be given to the patient until he is ordered out of bed by the surgeon. If he is dirty he is to be given a bath, if possible, and all his underclothing removed, and hospital clothing supplied in its place. In large general hospitals all the patient's private clothing is immediately sent to be disinfected in the large steam sterilizers built for the purpose, and the parts that need subsequent washing are sent to the laundry. After being cleaned they are packed away until the patient is convalescent. In small army hospitals no such disposition of the clothing is necessary, except in rare cases, where a soldier may accidentally bring contagious disease into the ward. In that case special instructions as to disinfection will be received. Ordinarily the clothing will be clean and can be locked up at once.

As soon as he is comfortably fixed in bed his temperature is to be taken, and note made of any noticeable symptom, such as chill, paleness of face, or difficult breathing. He will then be ready for the subsequent attention of the surgeon, and the further attentions of the nurse in carrying out instructions for treatment.

Kinds of Attention to Patients.—The kind of service that the nurse should render to the patient depends so entirely upon the degree and kind of illness that but few except the most general directions can be given applicable to all cases. Some of the soldiers sick in hospital are so slightly ill that scarcely any attention need be given them—they are fully capable of taking care of themselves. Other patients again are so sick that they cannot do a single thing for themselves. Beyond this there are cases of delirium, or patients in a very low condition, who not only cannot render themselves assistance but cannot tell their wants, and are so weak that they soil their bedding and clothing by involuntary discharges, and require constant supervision. Between these extremes there are all grades of cases requiring various degrees of care, and it is the intermediate cases which are often troublesome and irritating.

As a general thing the nurse is to consider that all the patients are under his immediate care and subject to his orders. This is a great responsibility, for sick men rely entirely upon the nurse. They lose courage, energy, and interest in themselves. They cannot, in severe illness, even think of themselves, all thinking must be done for them, and they must be managed as children. There is an indescribable feeling of perfect security a sick man experiences when he realizes that he is in the hands of a good doctor and a thoroughly reliable and efficient nurse. He knows that he is properly managed, and he begins to feel as contented as possible under the circumstances, and ceases to think of his troubles. These feelings bring with them the restfulness so important to recovery.

Cheerful Manner toward Patients.—It is expected of a military nurse to drop any disagreeable air of authority he may have assumed under the false impression that it is military. He is to cultivate that cheerfulness which experience shows is so necessary for the sick. With this cheerfulness there must go an assured manner which tells each patient he is sure to recover.

There is a great difference in this cheerful assurance of some nurses as contrasted with the dolefulness and timidity of others. Some have such a pleasing manner of doing all things that their very presence in a sick-room is a comfort.

As a general rule sick men are made worse by listening to the talk going on about other sick men and the dangers of such cases. This is one of the objections to having many sick people together where the melancholy or the sufferings of a few will make the others worse. Many invalids positively refuse to go to certain health-resorts because of the immense amount of suffering they would be compelled to witness.

As far as possible there should be no reference to any such subjects as dangerous and painful diseases. Of course it is impossible for the nurse to stop all such conversation, because men must and will talk of what is uppermost in their minds, and it would be foolish even to attempt to order them to stop. If the conversation is very evidently jarring on some sick man's nerves, of course it is perfectly justifiable then to order quiet in the ward, or better, report the matter for the steward's or surgeon's action. It is by his example that the nurse can do the most good. He should never allow himself to discuss these forbidden subjects in the hearing of patients who are still quite ill. The nurse's responsibility in this matter is just as great as the surgeon's, and we know that if the latter would speak in a patient's hearing of the dangers of his case, he would do very much harm. In civil practice a gossiping nurse is an abomination, and physicians always refuse to employ her as soon as they find her out, because they know that she does great harm by her imprudent talking.

Of course there never should be a word said to a sick man about the ability of the surgeon in charge. Such criticism is entirely uncalled for, and is not only a serious military offence in the hospital corps, but may do actual harm both to patient and surgeon. The nurse is not a doctor, and in his ignorance of what a good doctor really is, he can form only a worthless opinion on the subject. Often it happens that the surgeon is taking the best, and perhaps the only justifiable, course in a case, and because that course does not include some active measures, the patient may have a feeling of being neglected. Should this feeling be noticed the nurse's loyalty to his superiors should prompt him to soothe the patient as much as possible.

In military practice the attendance of the sick and wounded is purely an official duty, that must be performed by a certain person. Consultations are not recognized nor provided for in any way, and a change of physician is, of course, entirely out of the question. The surgeon must see the patient through to recovery. In view of this it is particularly improper for the military nurse to do anything, by word or deed, that would in the least affect the confidence the patient should have in his physician. This loyalty to superior officers must be inculcated as a part of the nurse's duty, though it is putting up too high a standard to expect it to be always observed.

There are tricks in all trades, and it seems to be a uni-

versal trick to criticise adversely every other man's work. It is hard to call in a mechanic in some lines, without having him say that the last work was a botch. Now nurses are prone to do this also by "running down" other nurses. The hospital corps is no place for any such practices, for no good can come of them. If a good word cannot be said of others, nothing should be said. If the soldiers get it into their heads that the nurses are careless and neglect their duties to the sick, the feeling of apprehension of getting worse may do more harm than the surgeon can do good. The nurses should understand this and have enough "esprit de corps" to feel that any disparagement of one reflects upon the others.

Confidential Relations of Nurses.—Should a nurse in civil life go to a new engagement and report her experience in her last engagement, divulge family secrets that have come to her knowledge, and make disparaging remarks about her employers or her patients, she is guilty of a most dishonorable action. She has been admitted to the house and treated as one of the family, and all her knowledge there gained is strictly confidential, and must be as closely guarded as the physician guards what is said to him.

Now all this is applicable to the army nurse in every respect. He knows of secrets about patients that the others constantly in the ward do not even suspect, and under no circumstances should he divulge these secrets. To be sure, it is impossible to get much privacy in army hospitals, and for this reason soldiers suffering from diseases which they wish kept secret will not come to the hospital, but will take any kind of treatment rather than run the risk of exposure. Now as it is desirable to do the soldier as much good as possible, it depends upon the nurse to aid the surgeon in keeping perfectly secret any confidential knowledge he may have, and try to mitigate that great publicity and lack of privacy which is inherent to the ward of an hospital. Worst of all, he should never boast of his knowledge of the patients as though he held them in his power. Such boasting is very low, and stamps the man as undesirable in the ward or anywhere near the sick. Nurses have been known to do this, and their influence is always bad.

The confidences between a patient and his nurse serve a very useful purpose in bringing to light certain symptoms that would otherwise be hidden. It occasionally happens that sick men, without either rhyme or reason, hold the doctor at such a distance that they are quite unwilling to talk freely to him. They have a false modesty in the matter although they have no hesitancy in talking to the nurse, hoping, and even knowing, that the matter will be at once brought to the attention of the doctor. The nurse thus becomes a medium through which valuable knowledge of symptoms is taken to the surgeon, who may at once act on this knowledge, and by tactful talking to the patients sweep away their unnecessary reserve and get a full and complete grasp of their cases. The above is not mere fancy, for every experienced nurse can remember instances of this natural modesty, though of course marked instances of it, except in venereal complaints, are quite rare among soldiers who have been living together for years with but little or no privacy.

It is curious also what persistence the sick will show in continually denying what they think reflects on their characters. Men will deny ever having had any venereal complaint when the scars of old chancres are in full view. The surgeon therefore is compelled to seek and get his information in all ways possible, for he cannot treat his patients by guess-work. It is the duty, then, of nurses to report facts coming to their knowledge confidentially, as they know such knowledge is a secret between them and the doctor.

Irritability of Sick Men.—The military nurse is particularly to be warned of the irritability of sick men. Everything in the way of insubordination is so quickly noticed in army life that the nurse is apt to misunderstand the natural peevishness of the sick. Special pains are therefore taken to explain the whole matter to the nurse, showing him why so many things are tolerated in the hospital ward which would not be tolerated in the barrack-room.

On the other hand, a nurse should not accept everything a patient will do, for such a course would be equally disastrous in certain cases. If a sick man sees that all his peevishness and restlessness is allowed to go unchecked he is apt to presume upon such leniency and get more peevish, unless he is too ill to have any thoughts in the matter at all. Therefore a gentle firmness is necessary in refusing requests that cannot be allowed. Without being cross, ugly, or mean, a nurse can give the patient firmly to understand that he must be quiet, as the orders are to that effect. Again, patients who are of an ugly, vicious disposition are apt to be deliberately bad in conduct. Where the nurse is sure that such conduct is deliberate, or has his doubts in the matter, he must report it at once to the steward or surgeon for action. Upon the nurse's tact and skill in managing these cases will depend in great degree his efficiency in the ward. Special care given to this point of the irritability of sick men is of so much importance that it is easy to see the greatest difference in the general order and contentment in the ward under some nurses, and the ill-feelings and unhappiness under others. The former are even-tempered men who understand the sick, while the latter are apt to be thoughtless or ignorant of this part of their duty. Occasionally a nurse will be so cross to the sick that he will actually retard their recovery. By giving thoughtful attention to the one item of irritability of sick men, a good nurse will be able to prevent much trouble in the ward and preserve that degree of order and quiet so necessary for men recovering from sickness.

Cleanliness of Patients.—It is a general rule that every patient, if his condition will permit, shall be given a bath upon his admission to the hospital. This rule is much less rigid in military than in civil hospitals, because soldiers are required to keep themselves clean by frequent bathing, and if they are not inclined to be clean about their persons their comrades are apt to compel them to be. It is very rare, therefore, to have a soldier admitted to hospital in a dirty condition, unless it is in the field after a long march without bathing facilities. In civil life the poor who are taken sick have probably had no bathing facilities, and when taken to the hospital are often in a filthy condition and must be bathed at once. In military hospitals in time of peace there is no need to be on the look-out for men who are dirty, but when one is found he must be attended to. In war times the reverse is true. After a long campaign, where the clothing has been limited in quantity, and changes could not be made, and bathing facilities were absent, the soldiers are apt to become indescribably dirty, and the heat, dust, and smoke of battle have made them far worse. The wounded are not infrequently brought to the hospital in a terrible condition of dirt, so that in war times the rule about bathing patients is of prime importance and is usually enforced wherever allowable.

After the patient has been in hospital for a few days the nurse is to look after his cleanliness, giving the necessary sponge-baths, looking after the hair and beard, and the condition of the nose and mouth. These duties are in no respect different from those in civil hospitals.

In war times it is quite common for soldiers to become infected with lice and "crabs," and on admission to hospital be an actual source of danger to the other patients. These cases may require the surgeon's care. It may be said that as a rule nothing will be of any use short of shaving hair from the face and head, under the arms and over the pubis. "Crabs" may be so numerous that the whole body, even the eyebrows and eyelashes, are infected. Though the eyebrows could be shaved off it may be requisite to pull out each hair of the brows or lashes having nits on them. The nits must be cut off and burned, for no drugs have any effect on them except such strong drugs as would injure the skin. Nits will hatch out in spite of all applications.

All matters relative to the cleanliness of the patient are within the personal duties of the nurse, and he should attend to them without special orders. The surgeon usu-

ally has many things to think of when he sees his patient, and must keep in mind dozens of different points in prescribing the treatment, so that his mind should not be distracted by finding the patient in a bad condition due to neglect by the nurse of those rules of cleanliness which he should carry out without special orders in each particular case. The same general directions are to be observed as in civil hospitals regarding cleanliness and neatness of the bed, bedding, and bedclothing. These are looked after, kept neat and clean, and protected from contamination by infective discharges. Very old army barracks are quite apt to become infested with bed-bugs, and the soldiers wage a constant warfare against them. Hospitals at such posts are liable to get the pests introduced by patients, and in such situations the nurse is taught to exert special vigilance and by frequent and ample use of insecticides to exterminate the pests as soon as their presence is known.

Observation and Report of Symptoms.—Military as well as civil nurses are required to observe the symptoms and report the facts to the surgeon. They must be taught that the patient is apt to exaggerate symptoms in certain cases and to hide them in others. The fact that a patient will make astonishingly erroneous statements as a result of dreams or slight delirium is to be kept in mind at all times. The military nurse is to be depended on in great part for that exact and detailed knowledge of patients necessary in military cases. In civil hospitals no special future harm may come to the patient, his relatives, or the community by the lack of records of any one case. It is entirely different in military hospitals, where every important fact in regard to each patient must be recorded for future reference. Years after a soldier's death or discharge from hospital his relatives may make claims against the Government, which may be grossly false on one hand, or deserving in the highest degree, and nothing except the most accurate hospital records will permit of justice being done. Thus it happens that the nurse is compelled to carry out the spirit of all those exacting detailed reports that are usually denominated "Red-tape."

Exaggeration of Symptoms.—There is a most important fact to be kept in mind by military nurses. In civil life where a man's pay depends upon the amount of work he does, and where he receives no pay if he is laid up by sickness, he is not apt to stop work for any trifling sickness. He goes on with his work willingly and cheerfully, even if he is slightly "under the weather," or suffering from slight injury. He knows that the matter is entirely in his own hands, and that no one can compel him to work. Laborers, therefore, become accustomed to working under difficulties, and it is astonishing sometimes to find under what disabilities they will go to their daily work. It is entirely different in military life, where every soldier knows that if he is able he must do his duty, whether he wants to or not. It would be a terrible state of affairs if, just before a battle, one-half of the soldiers would say that they are not feeling very well, and they guess they will lay off for a day or two. They must be excused by competent authority, and it must be made plain that they are not fit to work before they can be excused. The best soldiers never ask to be released from duty for any slight ailment, but there are a large number who feel very much aggrieved if they think they are working when they would "lay off" if they were their own masters in civil life. Under such circumstances it is human nature for a soldier to exaggerate his sufferings. It is not malingering, of which more will be said later, but is a natural and involuntary attempt on his part to make it clear to the surgeon that the ailment is enough to necessitate the man's name being placed on the sick report. Men who would not stoop to the meanness of malingering, and who would scorn a lie, will thus unconsciously deceive the surgeon as to the extent of their illness.

A man often thinks so much of his troubles that he thoroughly believes he is sicker than he really is. Now a man cannot always think of his troubles, and after he is comfortably fixed in the ward and excused from duty, and his mind is occupied with other things he cheers up if depressed, forgets his imagined pains, and shows by all his conduct that he is not very ill. If the nurse observes this man's actions in the ward he is able to give the surgeon accurate and reliable information that would be a great aid in determining the proper treatment. Without this aid the surgeon is apt to treat the man as more ill than he really is, and, by greater restrictions than are needed, he might be giving the patient unnecessary confinement and unnecessarily harsh treatment. It must be kept strictly in mind that it is not intentional on the part of the soldier to appear more ill than he is; and that he is an honorable man who wants to do his duty if he can.

By keeping these thoughts in mind the nurse is not apt to do him an injustice. As soon as the surgeon finds out the true state of affairs he can give the proper treatment and return the soldier to duty sooner than he otherwise would do. This course will save trouble and be far pleasanter to the soldier, who becomes satisfied he is better, and he returns to duty willingly in a very short time. This course is not only just to soldiers who suffer from slight ailments like all other human beings, but it is also just to the Government, because the man's labor is saved.

It must not be thought that the surgeon excuses a man only in cases of sickness that causes a civilian to stop work, for this is not so. For instance, a man with a bad sore throat may go to his work and get well, but a soldier in the same illness could not stand guard with the thermometer forty degrees below zero. So that men are often in hospital with trifling ailments that would get worse under the exposures to which they might be subjected.

Malingering.—By watching the symptoms of a case the nurse can often detect those mean men who deliberately state they are ill in order to escape duties which they are perfectly willing that their comrades should do for them. It is to the great credit of the American soldier that these cases of deliberate malingering are very rare, but now and then they do occur among the twenty-five thousand soldiers of our army. A malingerer occupies the valuable time of the surgeon, causes much unnecessary worry in trying to find out what is the real disease, causes a loss of valuable drugs and extra diet in the treatment, puts much unnecessary work on the nurses, and, if he goes undetected, causes better men of the company or troop to do extra guard or fatigue duty. It is only just to the good soldiers who are working extra that a malingerer should be detected and punished, and it is often due to an accurate, reliable, and just report from the nurse in charge that such detection is made possible.

In peace, soldiers very rarely try to keep themselves ill so as to escape duty. In war, so many men are being killed that a soldier is apt to welcome illness or injury that will enable him to get to a place of safety, and then go home, and possibly get his discharge. Hence it happens that occasionally a soldier may deliberately keep himself ill and refuse to take his proper treatment. To overcome this, it is customary to try such cases by court-martial. It may have to be shown to the court that the treatment was necessary to bring about a cure. Such trials are scarcely ever necessary in peace. In all cases the nurse may be an important witness to occurrences in the ward.

Administering Remedies.—In administering remedies there are usually no new directions for the nurse to observe, beyond the necessity for watching the patient to see that he actually takes the medicine that is ordered. Soldiers who come into the hospital for trivial complaints for the purpose of escaping duty, have an old, worn-out trick of pretending to take their medicines, when in fact they do not. They must be watched by the nurse.

As a rule, the stay of a soldier in hospital is made as pleasant as possible if he is ill. This is done in order to put nothing at all in the way of soldiers coming freely to the hospital for treatment as soon as they are taken sick. By such means it is possible to ward off serious illness, for it is highly probable that civilians who cannot easily stop work often suffer from serious complaints that could have been prevented by prompt treatment in the beginning. The old idea that the military

hospital should be made disagreeable and dismal to discourage malingering is brutal and not in accordance with modern methods. Nevertheless, in rare cases, just as in civil hospitals, disagreeable methods of treatment are resorted to, in the attempt to find out if there is malingering. In such cases bitter and disagreeable medicines may be ordered, and the nurse must exercise great care to see that the proper doses are actually taken. In all cases he is to be on the lookout for the standard tricks, and he must make it a habit to see that each dose of medicine is taken exactly as ordered.

Military hospitals are not furnished with all the modern conveniences for making medicines palatable, and the nurse must resort to various methods for overcoming bad tastes and odors. In the field there may be no facilities at all for fancy pharmacy. Pills may be covered with tissue-paper, powders mixed with sugar or clean drinking-water, citric acid lemonade be on hand for use after taking medicines, and various expedients resorted to as occasion arises. In the future no difficulty may be experienced, as the new field outfit contains medicines in tablet form ready for use.

4. Nursing in the Field.

Genera Convention.—Away back before the Crimean War there was started a crusade against the prevailing style of nurses. Before this time it was considered that such work must be relegated to widows and worn-out women who had partly failed in the struggle for existence. Indeed, the more ignorant and cruel the woman, the more apt was she to take up nursing in her decline. Perhaps Charles Dickens may have done much to start the reform against the Mrs. Gamps and Mrs. Prigs, by describing with such honesty their habits and ability. In the midst of this reform the Crimean War broke out, and to England was brought those horrible tales of the sufferings of the sick and wounded soldiers, from privations and poor nursing. That great woman, Florence Nightingale, who was then in the midst of the work of the great nursing reform, was sent to the Crimea and took charge of the hospitals. Her experiences in that war were written up, and the agitation resulting bore fruit in the Geneva Convention of 1864. This congress, composed of representatives from most of the civilized nations of the world, agreed to certain articles for the amelioration of the wounded in armies in the field. They were not concurred in by the United States until 1882, and even then with reserve as to the additional articles of 1868. The Convention is given in full below.

Original Convention.—Article 1. Ambulances and military hospitals shall be acknowledged to be neuter, and as such shall be protected and respected by belligerents so long as any sick or wounded may be therein.

Such neutrality shall cease if the ambulances or hospitals should be held by a military force.

Art. 2. Persons employed in hospitals and ambulances, comprising the staff for superintendence, medical service, administration, transport of wounded, as well as chaplains, shall participate in the benefit of neutrality, while so employed, and so long as there remain any wounded to bring in or to succor.

Art. 3. The persons designated in the preceding article may, even after occupation by the enemy, continue to fulfil their duties in the hospital or ambulance which they serve, or may withdraw in order to rejoin the corps to which they belong.

Under such circumstances, when these persons shall cease from their functions, they shall be delivered by the occupying army to the outposts of the enemy.

Art. 4. As the equipment of military hospitals remains subject to the laws of war, persons attached to such hospitals cannot, in withdrawing, carry away any articles but such as are their private property.

Under the same circumstances an ambulance shall, on the contrary, retain its equipment.

Art. 5. Inhabitants of the country who may bring help to the wounded shall be respected and shall remain free. The generals of the belligerent powers shall make it their care to inform the inhabitants of the appeal addressed to their humanity, and of the neutrality which will be the consequence of it.

Any wounded man entertained and taken care of in a house shall be considered as a protection thereto. Any inhabitant who shall have entertained wounded men in his house, shall be exempted from the quartering of troops, as well as from a part of the contributions of war which may be imposed.

Art. 6. Wounded or sick soldiers shall be entertained and taken care of, to whatever nation they may belong.

Commanders-in-chief shall have the power to deliver immediately to the outposts of the enemy soldiers who have been wounded in an engagement, when circumstances permit this to be done, and with the consent of both parties.

Those who are recognized, after their wounds are healed, as incapable of serving, shall be sent back to their country.

The others may also be sent back, on condition of not again bearing arms during the continuance of the war.

Evacuations, together with the persons under whose direction they take place, shall be protected by an absolute neutrality.

Art. 7. A distinctive and uniform flag shall be adopted for hospitals, ambulances, and evacuations. It must on every occasion be accompanied by the national flag. An arm-badge (brassard) shall also be allowed for individuals neutralized, but the delivery thereof shall be left to military authority. The flag and the arm-badge shall bear a red cross on a white ground.

Art. 8. The details of execution of the present Convention shall be regulated by the commanders-in-chief of belligerent armies, according to the instructions of their respective governments, and in conformity with the general principles laid down in this Convention,

Additional Articles.—Art. 1. The persons designated in Article 2 of the Convention shall, after the occupation by the enemy, continue to fulfil their duties, according to their wants, to the sick and wounded in the ambulance or the hospital which they serve. When they request to withdraw, the commander of the occupying troops shall fix the time of departure, which he shall only be allowed to delay for a short time in case of military necessity.

Art. 2. Arrangements will have to be made by the belligerent powers to insure to the neutralized persons, fallen into the hands of the army of the enemy, the entire enjoyment of his salary.

Art. 3. Under the conditions provided for in Articles 1 and 4 of the Convention, the name "ambulance" applies to field hospitals and other temporary establishments which follow the troops on the field of battle to receive the sick and wounded.

Art. 4. In conformity with the spirit of Article 5 of the Convention, and to the reservations contained in the protocol of 1864, it is explained that for the appointment of the charges relative to the quartering of troops and of the contributions of war, account only shall be taken in an equitable manner of the charitable zeal displayed by the inhabitants.

Art. 5. In addition to Article 6 of the Convention, it is stipulated that with the reservation of officers whose detention might be important to the fate of arms, and within the limits fixed by the second paragraph of that Article, the wounded fallen into the hands of the enemy shall be sent back to their country after they are cured, or sooner if possible, on condition, nevertheless, of not again bearing arms during the continuance of the war.

There are ten other articles, concerning the marine.

It is evident, therefore, that in the field, in civilized war, the military nurse is placed upon a very different footing than formerly. He is a privileged character because he is engaged in the work of humanity, and to proclaim his privilege he wears on his left arm the badge of his calling—the Geneva Cross—a red cross in a white field. When so employed, and so distinguished by his badge, he becomes neutral, notwithstanding his nationality, and he cannot become a prisoner of war. When his

work of bringing in or succoring the wounded is finished he must be sent back to his own army as soon as possible, unless he choose to remain and work among the wounded. In warfare with a civilized nation that has not agreed to the Geneva Convention, it plays no recognized part whatever, though its principles may be carried out by both sides on the general grounds of humanity. In war against savage people the humane principles of the Convention will be disregarded, and a nurse is apt to be killed in the very act of relieving the suffering. The hospital flag may be as much riddled with bullets as any other, and the very existence of medical help seems to be unknown to the savage. Thus it happens that as almost all the active operations of the United States army are against savages, the military nurse receives no benefit whatever from the Geneva Convention, and its provisions may not be taken into consideration at all.

On the March.—On the march the hospital corps detachment follows the regiment or brigade ambulances, the privates of the hospital corps being mounted. This is necessary to preserve their strength as much as possible, because their work begins at the end of the day's march, when the soldiers of the line can rest. Those that are not mounted are allowed to ride on ambulances or other wagons. The duties on the march are to look after the comfort of the sick that are being transported from camp to camp, give them their required medicines, prepare for them such food as may be practicable *en route* or on the short halts. On long, hot marches soldiers are apt to become exhausted and fall out of ranks to wait for the ambulances and the surgeon to come up. When such cases are met with the nurse secures their arms and accoutrements, places these in the ambulance, and then finds a seat for the patient and administers the remedies that have been prescribed. Cases of exhaustion are apt to be frequent when the campaign is proceeding under the difficulties of deficient and improper food and clothing, or the troops have been exposed to the severity of the weather. It can be assumed that in such circumstances the nurse may have much to do under great disadvantages.

In Camp.—On arriving at the end of the day's march the nurses all assist in making fires, preparing some light food for the sick, and making the latter comfortable in shady places, and attending to the usual routine duties of nurses. By the time this is finished the wagons with tents and rations have arrived; all hands must turn to and unload them as quickly as possible. The cooks secure the rations and start the preparations for the principal meal at once. All others erect the tents, prepare the cots or bunks for the sick, and carry the sick into the tents. This temporary field hospital is thus established, and can be placed in running order within a few minutes after the arrival of the wagons, and from this time on until the next day the duties of the nurse are essentially the same as in any permanent hospital.

There are so many things to be improvised in camp that it is almost useless to expect efficiency from the nurse unless he has had considerable experience as a camper-out, and has had much instruction besides. In the absence of bunks or cots he must know how to make a soft, comfortable bed of leaves or brush. He must know how to arrange the men in the tents so as to economize floor space. He must be thoroughly conversant with the methods of pitching tents, excluding draughts of air from patients, excluding rain, erecting and caring for the stoves in cold weather, and the thousand and one little details of camp life that altogether will turn a primitive way of living into one of great comfort. In the early morning, if camp is broken, some patients may have to be sent back as unfitted to proceed with the command. These must be prepared by the nurses, placed in the wagons with their accoutrements, and, if no nurse is to accompany them, they are to be given their medicines with instructions how to take them. The nurse is to do everything possible to make these men comfortable until they reach other hands. While this is being done the other patients that are to go forward are placed in the ambulances, and the tents are struck and everything loaded on the wagons and the march is begun.

In more permanent camps the nurses must be expected to devise conveniences for the sick. To go into this matter would only be to write an article on camping, which is not the intention here. It is sufficient to remark that in the months that might elapse before the camp is changed the nurses are continually making the field hospital nearer and nearer a permanent hospital of very rude construction. A nurse is expected to be handy with carpenter's tools, and ingenious enough to design from rough lumber and packing-boxes all the little appliances used in nursing. By a little ingenuity it is possible with the materials in camp to give efficient vapor-baths for the relief of spasmodic retention of urine, to make various forms of counter-irritation with hot water and hot stones, to practise the method of firing, to make poultices, and to perform numerous operations usually deemed to require special apparatus.

Battle.—When battle is expected the nurses are particularly busy in assisting to send the sick to the rear, and in getting everything ready for the work that is to come. Large quantities of fresh water are brought to hand, and as much water boiled as possible. The antiseptic solutions for irrigation are gotten ready, instruments and dressings brought out and prepared; indeed it is the whole routine of preparing for operation in a permanent hospital. It is a time of great excitement and hurry, and unless the nurses are well drilled and instructed there is apt to be abominable confusion. When the wounded are brought in, the nurse's duties are exactly as in permanent hospitals.

The arrangements made for succoring the wounded on the battle-field have been fully described in former articles in this work. Nurses detailed for duty at dressing, collecting, or ambulance stations have no new duties to perform that are not already described. Between these stations and the fighting line is an area where nursing ceases, and the privates are concerned in bringing in the wounded on stretchers, travois, etc., and in rendering first aid in the way of stopping hæmorrhage, reviving men from collapse, carrying water to the wounded, and all the other attentions to them that need not be detailed here.

In the rapid dusty marches previous to a battle there is no chance for cleanliness, and the soldiers become exceedingly dirty, as already explained. The wounds therefore are extremely apt to be infected, and the hurry, overcrowding, and lack of proper care, always make matters far worse. Thus it happens that wounds begin to suppurate or become gangrenous where they should heal kindly. This state of affairs is always seen in wars, and, as one of the means taken to prevent it, the nurses will be instructed to take the most particular pains to render everything aseptic and to be as cleanly as circumstances will permit.

In advances or retreats the nurse will be ordered to new fields of duty by his commanding officer, and in his work of humanity he will find himself greatly assisted by the provisions of the Geneva Convention which now come into play. From all the foregoing it can be assumed that the proper instruction of the nurse in field duties is to include all things that can be done for the sick, so that the wishes of the surgeon can be anticipated. By these means the corps of nurses will make it possible for a few surgeons to give medical and surgical care to a very large number of patients in such busy times as accompany and follow battles.

The future is to see a very great change for the better in the treatment and nursing of the wounded in the field. The advantage now taken by the concentrated medicines, extracts, compressed tablets, compact dressings, and intelligent methods of packing these in convenient shape has resulted in the magnificent new field equipment of the United States Army Medical Department. These are fully described in the last report (1892) of the Surgeon-General, and for convenience and efficiency this equipment is described as being in advance of that of any army in the world.

Going hand in hand with the advances in new medical

and surgical preparations is another advance, that of the preparation of food. This concerns us most here, as it is more intimately associated with the nursing of soldiers in the field. Ever since the most ancient times military men have been experimenting with the concentration and preservation of food for armies in the field. The results have not been of much service to the surgeon, as he could not utilize them to any great extent in the treatment of the sick. Recent years have seen the successful manufacture of a host of foods for invalids, and from these the soldier in future wars will derive incalculable benefit. It has been described above how soldiers are taken ill on the march, how they become exhausted and have to fall out, to be picked up by the ambulances. The great point in the treatment and nursing of these men is to give them rest, stimulants, and nourishment. The latter has always been lacking. In the future the ambulance will be fully equipped with some of the myriads of prepared foods now in the market. A cup of water will be heated on an oil or alcohol stove, and in a few minutes a cup of the most nourishing and stimulating soup can be prepared for the exhausted soldier. No doubt by such means it will be possible to restore to the fighting force numbers of men that in the past were sent to the rear or allowed to die in the roads. As soon as camp is reached the sick in the ambulances will be fed. This rest and nourishment will allow them to recuperate for the next day's work.

Again, it is known that for many hours, or perhaps days, the wounded on the battle-field may lie where they fall, and a large percentage of them die of exhaustion. Nurses and attendants will be enabled with these prepared foods to save a large number of such unfortunates. The nurse will therefore be instructed in the preparation and use of the foods that will be carried along with the ambulances, medicine wagons, or special ration wagons. Beef-extracts and prepared soups will, of course, be the main articles, but advantage will accrue also from the digested foods prepared for invalids, and indeed also from that immense list of specially prepared and concentrated vegetables and fruits for exceptional cases.

Chas. E. Woodruff.

MILITARY RECRUIT, PHYSICAL CHARACTERISTICS OF THE. The teaching in physical culture, and the encouragement that has been given to it by the various civil institutions of learning throughout this country and at the United States Naval Academy at Annapolis, Md., have, during late years, attracted much attention among army people, and have resulted in a revision, in certain particulars, of the standard of physical requirements for the admission of officers and enlisted men to the army, and of cadets to the Military Academy at West Point, N. Y.

The lax methods of examination that have heretofore been tolerated led to the acceptance of men with defects that were either latent or concealed, which, developed by incidents of the service, resulted in an early breaking down and consequent retirement of many officers, and to numerous discharges on disability certificates of enlisted men from the service. The remedy seemed apparent in the exercise of greater care when inquiring into the moral and physical qualifications of all classes of men, and in giving more explicit directions for the guidance of examiners in their work; to this end the recruiting regulations have been modified, the requirements for admission to the Military Academy at West Point have been more clearly set forth, and laws have been enacted by Congress providing for careful examinations into the physical condition of applicants from civil life for commissions in the army, and for similar examinations prior to the promotion of officers from one degree of rank to another. Many of the visual and aural defects that modern science has brought to light and defined are now officially declared as disqualifications, and tables of proportion, showing the relations which should exist between height, weight, and chest measurement and mobility in the normal man, are published as aids to the recruiting officer.

These several improvements in method are briefly outlined under the following headings:

THE LEGAL REQUIREMENTS FOR ENLISTMENT.—Any male person above the age of sixteen and under the age of thirty years, effective, able-bodied, and free from disease, of good character, who does not appear to be of intemperate habits, and who has a competent knowledge of the English language, may be enlisted, due attention being given to the restrictions in this article concerning minors. This regulation, in so far as it relates to age, does not apply to soldiers who may re-enlist, nor to those who have served honestly and faithfully a previous enlistment in the army. Applicants for enlistment are required to furnish such evidence of good character as they can obtain. With a view to determine their fitness and aptitude for the service, and to give them an opportunity to secure testimonials, as well as for the inquiry and deliberation contemplated by the Second Article of War, they may be retained and provided for at rendezvous, for a period not to exceed six days, after having signed the declaration of intention to enlist and passed the medical examination. Men so retained are known as *recruits on probation*. The enlistment papers of any such recruit who may be unfit or undesirable for the service, or who may not desire to remain in the service will not be completed. The enlistment papers of recruits who are accepted and duly sworn will bear the date on which the enlistment is *completed* by administering the oath (A. R., Art. LXXI., 908). . . . The Major-General commanding the army is of opinion that if satisfactory evidence of good character, habits, and condition cannot be furnished by the recruit, or be otherwise obtained, the presumption should be against him and he should *not* be accepted; and, further, that these views are concurred in by the Secretary of War and should govern in all cases (G. O., No. 1, Head-quarters Recruiting Service, 1890).

These rules and articles shall be read to every enlisted man at the time of, or within six days after, his enlistment, and he shall thereupon take an oath or affirmation in the following form: "I, A. B., do solemnly swear (or affirm) that I will bear true faith and allegiance to the United States of America; that I will serve them honestly and faithfully against all their enemies whomsoever, and that I will obey the orders of the President of the United States and the orders of the officers appointed over me, according to the Rules and Articles of War." This oath may be taken before any commissioned officer of the army (Article of War).

Every officer who knowingly enlists or musters into the military service any minor over the age of sixteen years without the written consent of his parents or guardians, or any minor under the age of sixteen, or any insane or intoxicated persons, or any deserter from the military or naval service of the United States, or any person who has been convicted of any infamous criminal offence shall, upon conviction, be dismissed from the service, or suffer such other punishment as a court-martial may direct (Article of War).

Under a recent Act of Congress fraudulent enlistment is declared a military offence, and is punishable by court-martial under the Sixty-second Article of War; the provisions of this law are fully explained to every applicant presenting himself for enlistment with the information that any person procuring his enlistment on or after the 25th day of September, 1892, by false representations or other fraudulent means, will render himself liable to trial and punishment by court-martial. "Fraudulent enlistment" is defined by the law officers of the department as "an enlistment procured by means of a wilful misrepresentation in regard to a qualification or disqualification for enlistment, or by an intentional concealment of a disqualification which had the effect of causing the enlistment of a man not qualified to be a soldier, and who but for such false representation or concealment would have been rejected."

The regulations above quoted sketch in outline the requirements for admission to the enlisted branch of the military service and the duties of officers in connection

therewith. For the recruiting officer an essential to success is a knowledge of men and their character, and for the medical officer a painstaking application of professional skill. The duty is a most important one, and in its faithful and thorough performance these officers share a grave responsibility. The influence of their judgment and discretion is felt throughout the entire military establishment, the efficiency of which depends in great measure upon the sound mental and physical condition and the intelligence of its enlisted force. From the varied classes and conditions of men presenting themselves for enlistment they are to eliminate not only those who are defective physically and mentally, but those who are defective morally, and if this duty be performed carelessly or indifferently, men will be admitted to the service with defects which will soon render them unfit for duty, or with moral obliquities that will induce malingering and desertion. Although the result of such perfunctory performance of duty may come to light during the probationary service of a recruit at a depot, it will certainly be shown in the company, from which his eventual discharge cannot fail to bring deserved censure upon the officers concerned in his enlistment.

Re-enlistments.—Soldiers who are unable to pass the required examination *in all respects* will not be re-enlisted without special authority from the Adjutant-General's Office, and then only for their former commands; application for such authority should be recommended only when it is shown that any existing defects will not prevent the full discharge of duty as a soldier, and that a continuance in service will be a positive benefit to the army.

Soldiers discharged as privates upon expiration of term of service and failing to re-enlist within one month, will not be again enlisted after they have passed the age of thirty-five years, unless for some good reason in the interest of the public service, and then only for their former commands upon special authority from the Adjutant-General's Office.

This limitation as to age will not apply to a soldier discharged as *a non-commissioned officer with excellent character*, and desiring to again enlist for assignment to a former command (not already full), either at the station thereof, or at a recruiting depot, provided he passes the required examination and furnishes satisfactory evidence in regard to character and habits since discharge.

Soldiers who have been discharged with good character under the provisions of law may be again enlisted without special authority after a period of two months from date of discharge, upon passing the required examination and furnishing satisfactory evidence in regard to character and habits since discharge, provided such enlistment is not barred by any of the above provisions.

Soldiers discharged before expiration of term of service for any other cause will not be again enlisted without special authority from the Adjutant-General's Office.

These restrictions, which are intended more particularly to govern re-enlistments for the line of the Army, need not necessarily be applied to the Hospital Corps; the approval of the Surgeon-General will be sufficient warrant for the re-enlistment of soldiers into that corps.

Height, Weight, and Chest Measurements.—"The *minimum height* of a recruit is at present fixed at five feet four inches for all branches of the service, although recruiting officers are allowed to exercise their discretion as to the enlistment of desirable recruits (such as band-musicians, school-teachers, tailors, etc.) who may fall not more than one-fourth of an inch below the minimum standard of height; the *maximum* height for the cavalry service is five feet ten inches; that for infantry and artillery is governed by the maximum of weight, to which should be applied the rule for proportion in height."

"The *minimum weight* for all recruits is 128 pounds, except for the cavalry, in which enlistments may be made without regard to a minimum of weight, provided the chest measurement and chest mobility are satisfactory. The *maximum* for infantry and artillery is 190 pounds; for cavalry and light artillery, 165 pounds."

The standards of height and weight are, however, subject to change, instructions to that effect being issued from the Adjutant-General's Office "from time to time as the requirements of the service may dictate."

These standards are based upon results obtained by skilled observers who, after careful study and the examination of large numbers of men in civil and military life, have established the fact that there is an *average proportion* in healthy, fully developed men between the height, weight, chest measurement, and chest mobility which will admit of slight variations without indicating a departure from health. The rules of this proportion may be formulated as follows:

For each inch of height from 5 feet 4 inches to 5 feet 7 inches, inclusive, there should be calculated 2 pounds of weight. When the height *exceeds* 5 feet 7 inches, calculate 2 pounds of weight for the *whole number* of inches of height; add to this product 5 pounds of weight for each inch of difference between 5 feet 7 inches and the actual height; the sum will be the normal weight in pounds.

The *chest measurement at expiration* in men from 5 feet 4 inches to 5 feet 7 inches in height should exceed the half height about half an inch; in those from 5 feet 8 inches to 5 feet 10 inches it should *equal* the half height, while in those from 5 feet 11 inches upward it should be slightly *less* than the half height.

The *chest mobility—i.e.*, the difference between the measurement at inspiration and expiration—should be *at least* 2 inches in men below 5 feet 7 inches in height, and 2½ inches in those above that height.

The following table shows this concisely:

Height.	Weight. Allow for each inch of height:	Chest measurement.	Chest mobility.
5 feet 4 to 5 feet 7 inches.	2 lbs.	Half height plus half inch.	2 inches.
5 feet 8 to 5 feet 10 inches.	2 lbs., and 5 lbs. additional for each inch over 5 feet 7 inches.	Half height.	2½ inches.
5 feet 11 to		Slightly less than half height.	2½ inches.

For example, a man who measures 5 feet 4 inches should weigh 128 pounds—*i.e.*, 5 feet 4 inches = 64 inches; 64 × 2 = 128, the normal weight. He should have a chest measurement of 32½ inches at expiration, being half height; 32 inches plus ½ inch = 32½; the chest mobility should be about 2 inches.

A man who measures 5 feet 9 inches should weigh 148 pounds—*i.e.*, 5 feet 9 inches = 69 inches; 69 × 2 = 138; difference between 5 feet 9 inches and 5 feet 7 inches is 2; 2 × 5 = 10; 138 + 10 = 148, the normal weight in pounds. He should have a chest measurement of 34½ inches (his half height), and a chest mobility of at least 2½ inches.

It is not necessary that the applicant should conform *exactly* to the figures indicated in the rules, a variation of a few pounds from either side of the standard in the minimum, medium, and maximum weights, and of a fraction of an inch in chest measures being permissible if the applicant is otherwise in good health and desirable as a recruit. The rules are given to show what is regarded as a fair proportion, *but the weight must be at least* 125 *pounds*, except when less is especially authorized by the superintendent or the Adjutant-General.

In such cases the recruiting officer's reasons and the superintendent's order should be noted in full on the enlistment papers. Any *considerable* disproportion, however, of *height* over *weight* is cause for rejection; but a marked disproportion of *weight* over *height* does *not* reject unless the applicant is positively obese.

In order that an intelligent application of these rules and their variations may be made, the attention of recruiting officers is called to the manner in which a man's height is made up.

The chest, containing the heart and lungs, is the most important division of the body. It contains the vital

machinery and represents the *staying power* of the man. It must, therefore, be ample. The function of the legs is to transport the body; they should be well formed and sufficient, but not unduly long, for length of limb at the expense of the chest is a disadvantage. A long-legged, long-necked man with a short chest is objectionable as a recruit.

The average height of a youth of eighteen years of age, a "growing lad," is a little over 5 feet 4 inches, and increases gradually until he reaches the age of twenty-five years—the stage of physical maturity or manhood—when his average height is between 5 feet 7 inches and 5 feet 8 inches.

During the growing period the frame-work and vital organs receive their proper development, and considerable departures from the given average of proportionate height to weight indicate an impairment of these organs which may, and probably will, develop into positive disease after exposure to the hardships incident to the life of a soldier; hence they are of greater significance in men of these heights than in taller men, who are presumably of greater age and more mature growth.

After twenty-five years of age, the body being fully developed, the excess of nutritive material over and above that required for its maintenance in health is deposited in the tissues as fat, and it will be found that a disproportion of weight over height occurs usually in adults or men in middle life. It is rare to meet in the recruiting rendezvous with *very* fleshy *young* men.

The following table is given for convenience of reference:

TABLE OF PHYSICAL PROPORTIONS FOR HEIGHT, WEIGHT, AND CHEST MEASUREMENT.

Height.		Weight.	Chest Measurement.	
Feet.	Inches.	Pounds.	At expiration: inches.	Mobility: inches.
$5^{4}/_{12}$	64	128	32½	2
$5^{5}/_{12}$	65	130	33	2
$5^{6}/_{12}$	66	132	33½	2
$5^{7}/_{12}$	67	134	34	2
$5^{8}/_{12}$	68	141	34	2½
$5^{9}/_{12}$	69	148	34½	2½
$5^{10}/_{12}$	70	155	35	2½
$5^{11}/_{12}$	71	162	35¼	2½
6	72	169	35¾	2½
$6^{1}/_{12}$	73	175	36¼	2½

A deviation from the rules of physical proportions may be made in the examination of candidates for admission to the United States Military Academy at West Point, and for members of the graduating class, whenever this is deemed desirable by the Medical Examining Board.

THE EAR.—Recent instructions from the War Department require that all men enlisted for the artillery arm of the service at a military post, or assigned to that arm from a depot, shall, before such enlistment or assignment, besides undergoing the ordinary examination, be examined especially with a view to establishing the fact of the patency of the Eustachian tubes and the integrity of the tympanic membranes, in default of which the men are unfit for that arm.

PHYSICAL EXAMINATIONS OF CANDIDATES FOR APPOINTMENT AS CADETS AT THE MILITARY ACADEMY AT WEST POINT, N. Y.—The physical examination of candidates for appointment to the United States Military Academy will be made after the methods prescribed in "Greenleaf's Epitome for the Examination of Recruits, and as they are final for admission to the Military Academy special care should be given to determine the condition of the heart and lungs. Normal vision ($\frac{20}{20}$) as determined by the official test types is required, and color-blindness rejects. The following rule for proportionate height, weight, and chest measurement, is substituted for that on pages 26–28 of the "Epitome," but it should be understood that this rule is intended *merely as a guide*, from which deviations are permissible in the judgment of the medical officer:

Rule.—For each inch of height, from 5 feet to 5 feet 7 inches, calculate 1.85 pound of weight; above 5 feet 7 inches, add to this standard 5 pounds for each inch of height; minimum chest measurement at expiration, from 5 feet to 5 feet 7 inches, half the height plus half an inch; from 5 feet 7 inches to 5 feet 10 inches, half the height; from 5 feet 10 inches upward, slightly less than half the height; minimum chest mobility, 2 inches. In exceptional cases a minimum weight of 105 pounds may be accepted.

Under recent regulations the examinations are held at the military post nearest the residence of the candidate, and simultaneously with the mental examination.

Medical officers are instructed to record in each case, whether of acceptance or rejection, the results of their examinations on a form of which the following is a copy:

To be sent to the Surgeon-General, United States Army.

FORM FOR THE PHYSICAL EXAMINATION OF A CADET CANDIDATE FOR ADMISSION TO THE U. S. MILITARY ACADEMY, WEST POINT, N. Y.

This examination is to be made before the candidate is stripped.

Name; birthplace; residence.

Nationality of father; of mother. If either or both parents, or brother or sister have died, state the cause.

Do you drink intoxicating liquors, and, if so, to what extent? Do you use tobacco, and, if so, in what form and to what extent?

What diseases or injury have you had, if any?

Vision: Right eye; left eye. Color perception.

Hearing: Right ear; left ear.

This examination is to be made after the candidate is stripped.

Physique.

Age.		Height.		Weight.	Chest measurement.	
Years.	Months.	Feet.	Inches.	Pounds.	Expiration.	Inspiration.
					inches	inches

Nutrition and Diathesis.—Note anything unfavorable in the general appearance, such as sickly aspect or unduly full habit.

Integumentary System.—Note any skin eruptions, sores, or ulcers. Any tendency to catarrhs?

Nervous System and Organs of Sense.—Note any loss of faculties or other present derangement of function or any suspicion of serious lesion.

Respiratory System.—Note any hoarseness, cough, or other present derangement of function, or any abnormity discoverable by auscultation or percussion.

Vascular System.—Note rate and quality of pulse. [*If excited, re-examine till you assure yourself of the normal rate.*] Any intermittence or irregularity, or undue strength or weakness of heart-action? Any abnormity discoverable by auscultation or percussion? Any hæmorrhoids, varicocele, or varicose veins?

Digestive System.—Note any present derangement of function, any enlargement of liver or spleen, or suspicion of organic disease of any of the abdominal organs.

Remarks.

I certify that have personally examined the above-named candidate, and, finding him physically qualified for the military service, (accept, reject) him.

Surgeon, U. S. Army.
Surgeon, U. S. Army.

Dated at , this day of , 189 .

Charles R. Greenleaf.

MOFFAT. A watering-place in Dumfries-shire, Scotland.

LOCATION.—Moffat is a village charmingly situated among the lower hills of Scotland. It has a cold, sulphurous, and saline spring of small importance, but is popular on account of the exhilarating and bracing quality of its atmosphere, and its general salubrity as a summer resort. Mineral-water baths are much employed, and there is a hydro-therapeutic establishment of modest equipment. The water contains sulphuretted hydrogen and has a disagreeable taste. Fogs are said to be rare at Moffat, but there is plenty of rain. The place is patronized by the Scotch and English, and is by them very highly spoken of; but it has not yet acquired an international reputation. Summer season only.

Edmund C. Wendt.

MONOBROMACETANILIDE (Antisepsine, Asepsine). Very soon after the therapeutic value of acetanilide had been recognized, this bromine compound was introduced as an anodyne, analgesic, and antiseptic. It is

formed from acetanilide, $C_6H_5NHC_2H_3O$, by the substitution of one atom of bromine for one of hydrogen, its formula being $C_6H_4BrNHC_2H_3O$. It occurs in white acicular crystals, and is tasteless; it is insoluble in water, slightly soluble in glycerine, and very soluble in alcohol and ether.

In doses of five-sixths of a grain, four times a day, it lowered the temperature in phthisis, typhus, and typhoid fever, slowing the pulse at the same time, but not affecting the respiration. In pneumonia it was found liable to produce cyanosis. It was also used in neuralgia with success, in doses of five to eight grains.

The employment of this compound failed to become general, as it was found that prostration and cyanosis frequently accompanied its use. Several cases have been reported, in which two doses of five grains, taken at long intervals, produced very alarming symptoms. Lips, cheeks, and extremities became cyanosed, pulse rapid and small, noises in the head, and great restlessness and weakness. These symptoms diminished in a few hours and recovery followed in all the cases.

As an application to wounds and ulcers it is thought to promote healing in a remarkable manner. It also was used to allay the pain of hæmorrhoids and anal fissure, in the form of suppositories. *Beaumont Small.*

MONOCHLORPHENOL. A derivative of carbolic acid by substituting one atom of chlorine for one of hydrogen; its formula is C_6H_4ClOH. It is a very volatile liquid, giving off vapors which are heavier than air. Under the name of *chlorphenol*, a mixture of monochlorphenol, alcohol, eugenol, and menthol, has been recommended as an inhalation in phthisis and pulmonary troubles in which an antiseptic is likely to prove serviceable. Dr. Passerini, of Casate-Nuovo, Italy, who introduced it for this purpose, has used it in a number of cases with beneficial effects. He states that it is a powerful antiseptic, free from caustic and irritant properties. Fifteen to thirty drops are to be placed on a pledget of cotton in an inhaler, and the fumes inspired; being heavier than air they are supposed to penetrate deeply into the bronchioles and alveoli. In cases in the incipient stage of phthisis the sputa were found to diminish and lose their purulent character, and in two months the patients were apparently cured. The advantages he claims for it are: 1, The inhalations are easily borne in advanced phthisis, and they are convenient of application; 2, no injurious effects arise from the continuous use of the drug; 3, changes in the quantity and quality of the pus continue until pus and bacilli disappear, the cough diminishing, the fever being reduced, the appetite and sleep soon returning, the weight of the body increasing rapidly, and local improvement being speedily attained.
Beaumont Small.

MONTE CARLO. This Riviera resort is one of the most beautiful places along the north shore of the Mediterranean. It is also one of the best sheltered spots, and would probably be the leading health-resort of the whole coast if it were not for the notorious gambling palace erected there. Monte Carlo is part of the little principality of Monaco, and is only nine miles in an easterly direction from Nice, and about six miles westward from Mentone.

Although Monte Carlo is chiefly visited by the votaries of pleasure, real invalids have of late years been attracted to the place on account of its undeniable advantanges as a winter station. In connection with the institution of public gambling, the writer will here quote from his report on Monaco and Monte Carlo, which appeared in the *Medical Record* of July 23, 1892:

"My experience on the Riviera enables me to state as a positive fact that many more people go to Monte Carlo to gamble from the various resorts near it than from the town itself. Cannes, Nice, Mentone, and even San Remo, send their daily quota of gamblers there in uncomfortably crowded trains. And those who have no inclination for the silly game may just as well live within a stone's throw of the Casino itself as miles away. I cannot, therefore, quite agree with those who would warn people away from Monte Carlo merely on account of the gambling going on there. If they are so weak as to have to yield to this particular temptation, they are better off at home than on the Riviera. It has seemed to me, however, that Americans are abundantly able to take care of themselves wherever they may happen to be. It is necessary to state my views on this point, because I believe Monte Carlo can be made one of the best winter stations on the whole coast. Even now every possible accommodation is offered there, and the only criticism one can justly make on that score is that the hotel and restaurant rates are often exorbitant. But if it is not a cheap place, it certainly can claim to be a good one, at least so far as the provision of American comforts and luxuries is concerned. This is considerably more than can be said for some other winter stations that are scattered along the coast here."

In the same report the writer has also pointed out that Monte Carlo is one of the warmest winter stations on the Mediterranean coast. But it is not true that it enjoys a more equable temperature than all other resorts. Sudden thermometrical variations occur there just as elsewhere on the Riviera. Some parts of the principality are very well protected from winds, while others are decidedly exposed to them. The bare rocks rising up to a considerable height, immediately back of Monte Carlo, afford ample protection from cold northerly winds, and by reflecting the sun's rays appreciably raise the temperature in their vicinity. But when the sun has set, the succeeding chill is felt all the more violently, though the actual fall of temperature is less abrupt and less perceptible than our sensations appear to indicate. It would occupy too much space to go into details here concerning the physical configuration of various sections of the Monégasque territory, but the reader may infer from these general indications that some well-sheltered and warm nooks can be found at Monaco. For well-to-do invalids the place will doubtless be made increasingly attractive, on account of the large sums of money spent annually for improvements. But people don't save money by going there, even when they gamble and win.

The rainfall and the proportion of sunny days to cloudy ones are about the same as at Nice or Mentone, and need not be specially considered. One advantage in favor of Monaco is that less dust is found there than at Nice, Cannes, or Hyères.

The drinking-water of Monte Carlo was not good at the time of the writer's tour of inspection. But it was about to be changed for a better supply. As regards the sewerage of the place, although an elaborate and expensive system of street drains exists, it is not as perfect as the authorities claim. As Monte Carlo and Monaco are rapidly growing this is a matter of great importance to their future claims as health-resorts.

In the writer's article already alluded to, this point is referred to as follows: "Excepting the low-lying quarter called Condamine, Monaco affords every natural advantage for a perfect system of drainage. Yet so far from being in good shape, this essential sanitary requirement leaves much to be desired here. It is true, drains have now been established in all the principal streets, and most of them have a sufficient natural incline. But, as elsewhere on the Riviera, the house connections are insecure and dangerous. This applies more particularly to the old house-pipes that were subjected to the violent shaking up of the earthquake a few years ago. The authorities are only just beginning to realize that, in spite of the prevalent English closets, some radical reforms may be needed.

"Many of the old, poorly constructed, unventilated cesspools still exist, and receive the house-soil. As plenty of water is now used they would have to be emptied every two or three weeks. But house-owners, in order to avoid this expenditure, have, in spite of forbidding law, connected their cesspools by overflow pipes with the main sewers. Cut-off traps having been quite generally omitted, the obvious consequence is that sewer-gas is almost certain to enter all hotels, villas, and lodg-

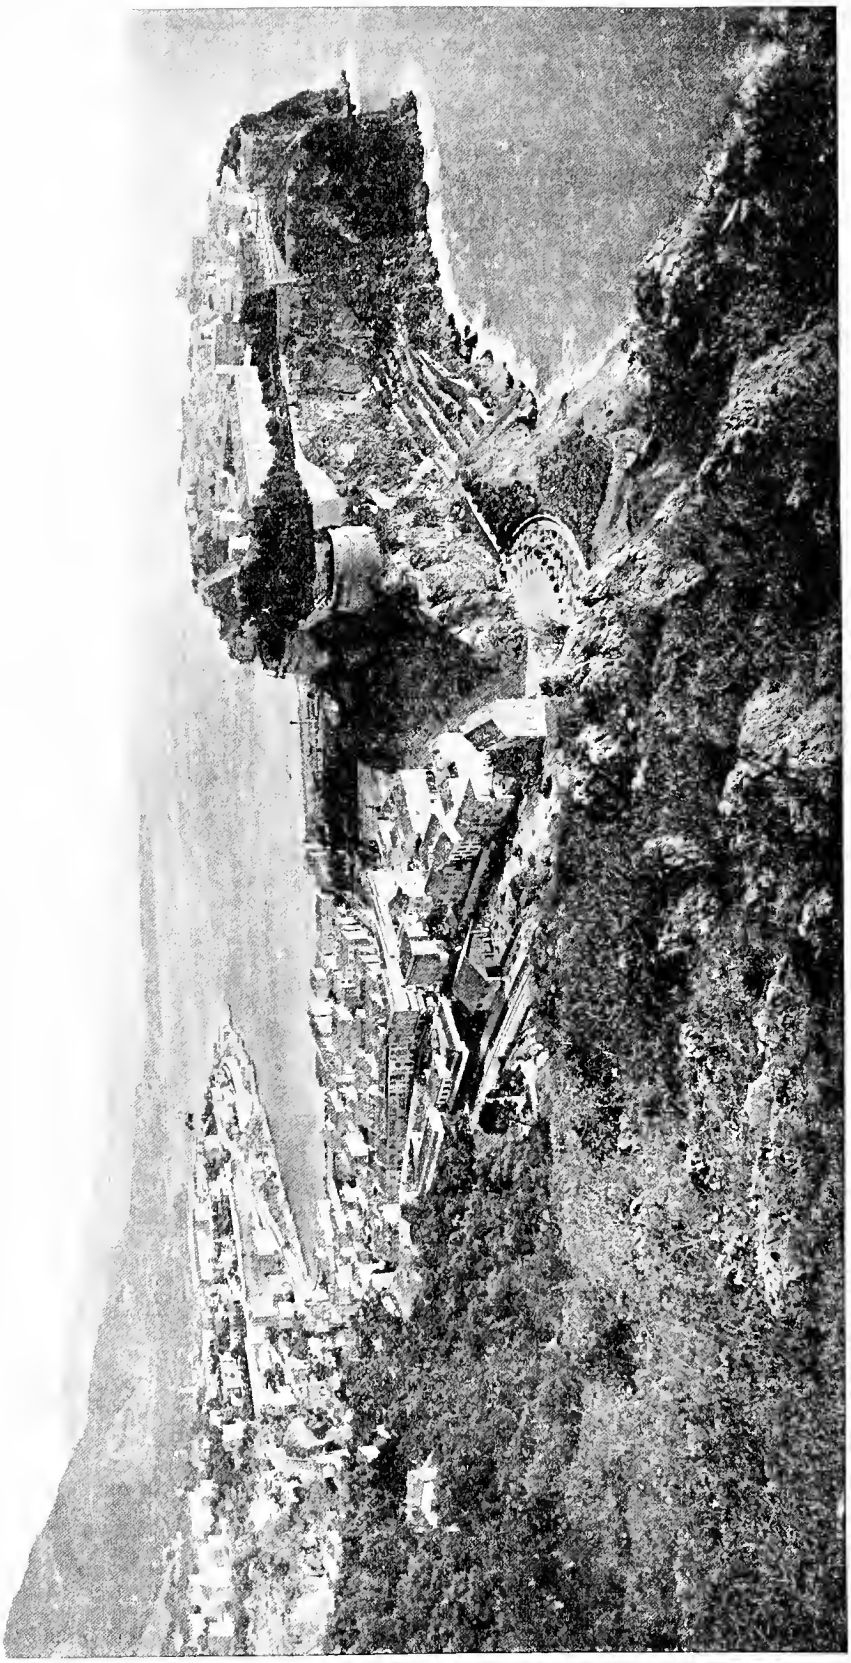

FIG. 430.—View of Monaco and Monte Carlo.

ing-houses provided after this obsolete fashion. The evils of so reckless a system are to some extent counteracted by the winds that cleanse the polluted atmosphere. But the night-air of such dwellings is bound to be dangerous, and, whenever possible, windows ought to be kept open all night. I am bound to state, however, that offensive odors, such as are so often justly complained of at Nice, are only rarely experienced at Monte Carlo. But Nice is eight times the size of Monaco, as regards population, and as the latter place grows, the present evils are sure to augment, unless proper precautions are taken.

"The sewers, intended only for surface waters, now discharge into the landlocked little harbor, which is an additional nuisance, fraught with potential danger for this place. In regard to the provision of amusements, more particularly concerts and theatricals, Monte Carlo stands without a rival on the Riviera."

Patients should always be warned against visiting the Casino, even as lookers-on, for the dust-laden, stifling air of the unventilated rooms is responsible for many illnesses which could have been avoided.

The indications for spending a winter season at Monte Carlo or Monaco do not differ from those which apply to the Riviera generally, and the reader is accordingly referred to the article on this subject which appeared in Volume VIII. of the HANDBOOK. With Americans Monte Carlo is a favorite resort, and one is sure to meet numerous countrymen there every winter.

Edmund C. Wendt.

MONTMIRAIL. A watering-place in the Department of Vaucluse, France.

LOCATION.—Montmirail-Vacquarais is a small village, possessing several purgative and one chalybeate spring. It is not well known outside of France, but as the really efficacious waters are now exported in large quantities, it will probably soon acquire more of an international reputation. The place is pleasantly situated between Orange and Carpentras.

ACCESS.—The village of Montmirail is reached by way of Orange, on the Paris, Lyons & Mediterranean Railroad. It is one and one-half hour's drive from the station.

ANALYSIS.—The principal spring of Montmirail is rich in sulphate of magnesium, and resembles the celebrated Seidlitz and Pällna waters. According to Mr. Henry one thousand grammes of the *Source verte* contain:

	Grammes.
Sulphate of magnesium	9.31
Sulphate of soda	5.06
Sulphate of lime	1.09
Chloride of magnesium	0.83
Chloride of sodium	0.18
Chloride of calcium	0.18
Bicarbonate of lime	0.37
Bicarbonate of magnesia	0.16
Calcareous phosphates, silica, alumina, sesquioxide of iron, and arsenical principle	0.39
	17.30

Traces of iodides, salts of potash and ammonia, and organic matter.

The sulphate of magnesium imparts a decidedly bitter taste to the water, but purgation is not accompanied by griping pains or other signs of intestinal irritation.

INDICATIONS.—These waters are chiefly employed in gastro-intestinal affections with a tendency to constipation, in dyspepsia, abdominal plethora, diabetes, and affections of the spleen, and in some of the constitutional effects of malaria. Season, May to September.

ACCOMMODATION.—There is only one bathing and thermal establishment with a fairly good equipment. The boarding arrangements are on a modest scale. There is an absence of fashionable life.

Edmund C. Wendt.

MOUNTAIN SICKNESS. Ger., *Bergkrankheit;* Fr., *Mal des Montagnes;* Sp., *Puna* (?). Mountain climbers have often described a peculiar train of symptoms from which they suffered in first ascents after reaching a certain height above the level of the sea, and which systematic medical writers have grouped together under the name of mountain sickness. The first mention we find of the ailment was made over two centuries ago, but for a long time no special attention was paid to it, as it was supposed to be due merely to the unusual exertion of climbing, and to be nothing more than a form of fatigue. Within the past fifty years, however, several writers have described the affection at length, and have even made ascents for the sole purpose of studying it, analyzing the symptoms observed, and endeavoring with more or less success to discover the true cause of their production. Notwithstanding that the facts upon which our knowledge of mountain sickness is based, and which have led writers to regard the affection as one *sui generis* and due to a specific cause, have, as was just mentioned, been accumulating for more than two centuries, and have been collected by scientists in special excursions made for that special purpose, they are even yet fragmentary and insufficient to warrant the formulation of a definite and satisfactory explanation of the symptoms.

Among the most recent observers of mountain sickness was Mr. Edward Whymper, who made ascents of some of the highest peaks of the Andes with the avowed object, among others, of gleaning some new facts bearing upon the effects of high altitude upon the human body. He did not accomplish this object as fully as he had hoped, for, although he made twelve ascents to various heights, he suffered from but one pronounced attack of the malady. This occurred during his first ascent, and appeared suddenly when his party had reached an elevation of 16,664 feet (barometric pressure 16.510 inches). He and his two Swiss guides found themselves suddenly incapacitated for work of any kind. Respiration was hurried and was accompanied by spasmodic gasps or gulps. All suffered from intense headache and a feeling of general malaise and exhaustion. The dyspnœa seemed to be the most marked feature of the attack, for the sufferers could breathe only with the mouth wide open; conversation was abandoned, being literally a waste of precious breath; smoking became distasteful, and was moreover too difficult of accomplishment to be indulged in, even had it been otherwise desired; eating was impossible, because of the interruption thereby occasioned to the one important occupation of breathing; and even fluids had to be taken sip-wise and as it were in stolen moments between gasps. The temperature was somewhat elevated (38° C., or 100.4° F.), and the pulse was markedly accelerated. Recovery was very gradual, and indeed was not complete until the party had descended to their camp, at some distance below the point where they had experienced the attack. Even after recovery seemed to have fully taken place, Mr. Whymper says, he remained very weak, became easily fatigued, and was troubled with shortness of breath on the slightest exertion. None of the party suffered from nausea or vomiting, but this may have been because they were all so "knocked out" that they were incapable of any exertion, and possibly they might have had some pronounced gastric symptoms had they been able to move about at all, and thus tax their little remaining strength.

This attack was experienced upon the occasion of the first ascent of Chimborazo, and, as before mentioned, at an elevation of a little over 16,500 feet. But it never recurred in any of the eleven subsequent ascents (one of them up Chimborazo again), although at one time they reached a height of 19,500 feet (barometer, 14.750 inches). They were able to remain at this elevation for twenty-six hours "without any serious inconvenience," although in all their ascents they experienced more or less lassitude and some dyspnœa, being always compelled, when in movement, to breathe with the mouth open.

In looking about for an explanation of the phenomena of mountain sickness, Mr. Whymper naturally finds it in the diminution of atmospheric pressure, in the operation of which, however, he distinguishes two factors, one permanent in its action and unavoidable, the

other temporary. The permanent factor, and the one for which he thinks it improbable that tolerance could ever be established, is the reduced value of the air that can be inspired by ordinary efforts in a given time. As a result of this it becomes necessary to inhale a much larger quantity of air, and therefore to make habitually a greater number of inspiratory efforts in a given time, in order to bring to the blood circulating through the pulmonary capillaries a volume of oxygen equal to that supplied to it by ordinary respiration nearer the level of the sea. The second factor is the reduced pressure upon the surface of the body, as a result of which the air or gas within the body expands and presses with more or less force upon the internal organs. The symptoms so produced are temporary, and pass away as soon as the equilibrium is re-established between the internal and external pressure, and they may even be avoided altogether by making the ascent very leisurely, and pausing at frequent intervals to permit of a modification of the pressure within the body sufficient to equalize it to that of the surrounding atmosphere.

Although Mr. Whymper's observations were carefully and intelligently made, they are less useful as a contribution to the literature of the ailment than they might have been had he not been an experienced mountain climber. Both he and his guides had made numerous Alpine ascents, and had thereby become more or less acclimated, if such expression may be allowed; and as a result the affection was not manifested in them to the same degree that it would have been in others unaccustomed to exertion at great elevations above the sea-level. One of the characteristics of the malady is that, as a general rule, it affects a person severely only upon his first ascent to a height of from ten thousand to fifteen thousand feet. The second time the symptoms are usually less pronounced, if too long a time have not elapsed since the first ascent; and when frequent excursions are made at short intervals, the system becomes so adapted to the changed conditions that the unpleasant symptoms of the malady are no longer manifested. Expert mountaineers seldom experience any inconvenience save under very exceptional circumstances, as for example when ascending to an unusually great elevation, or when suffering from the effects of some debilitating condition.

The first symptom noticed is an increased rapidity of respiration, with a feeling of constriction of the chest. The pulse is accelerated and there may be some irregular action of the heart; a sense of fulness and pressure in the head, increasing at times to a throbbing pain, is present, and the person complains of a peculiar weakness of the legs, sometimes accompanied by rather sharp pains in the knees. Ordinarily these early phenomena are of slight intensity, and may be dissipated by taking a few deep inspirations. Not so, however, if the individual persists in his determination to ascend beyond this point. Under the combined influence of increasing rarity of the atmosphere and of continued muscular exertion, the symptoms grow more and more severe, new ones of a more grave character appear, and finally the sufferer is compelled by sheer physical exhaustion reluctantly to give up the struggle and acknowledge himself beaten by the quiet but invincible forces of nature. Rest, especially in a recumbent posture, affords relief at once to the more pressing symptoms and gradually effects a cure of the ailment, even though the person do not descend to any lower level. The improvement is often, however, very slow, and the less distressing symptoms, such as moderate dyspnœa and a feeling of fatigue on slight exertion, may persist for days, or even weeks.

The severer manifestations of the malady are of two classes, the one seemingly due to insufficient oxygenation of the blood, and the other resulting from diminished atmospheric pressure. In the first category we find, in addition to the shortness of breath, drowsiness and lassitude, vertigo and the appearance of black spots before the eyes, intense cephalalgia, eructations, and frequently nausea and vomiting. There is usually also considerable thirst, accompanied by a feeling of dryness of the mouth and fauces. The weakness of the legs and sense of fatigue increase, until the patient becomes utterly exhausted and incapable of any further exertion. At the same time the reduction of atmospheric pressure causes a fulness of the venous system. The superficial veins of the exposed portions of the body are visibly swollen, and hæmorrhages frequently take place from the mucous surfaces. Epistaxis is common, and in aggravated cases bleeding from the stomach and intestines has been noted. Dr. Pöppig, who lived for a number of years at Cerro de Pasco, Peru, some 14,500 feet above the level of the sea, has stated that new arrivals there were often unable to shave for the first few days of their stay, owing to the extreme tendency of the skin to bleed. He mentions also an instance of a person who was forced to give up playing on the flute, as every attempt to do so caused him to spit blood. If all the inhabitants were similarly affected, it will be conceded that an exile at Cerro de Pasco would not be without its compensations.

The process of acclimatization is apparently a slow one, when the individual remains constantly at so great an elevation, for Dr. Pöppig says that no European is able, during the first year of his residence at Cerro de Pasco, to exert all his former strength, and it is only gradually, in the course of the second year, that he acquires ability to do so.

Mountain sickness appears much earlier and is more pronounced in those who are walking than in riders. Aëronauts can ascend to much greater heights without suffering than can mountain climbers, for they are sitting quietly in the car of the balloon and are husbanding their breath. So it is, in less degree, with riders or those travelling up the mountain side in wheeled conveyances. Thus Dr. Esserwein tells us of a journey he made by rail from Callao up to a town in the mountains lying at an elevation of about 11,500 feet above the sea. While sitting quietly in the car he felt no inconvenience, but immediately upon alighting at the station he was seized with dyspnœa, constriction of the chest, rapid and irregular pulse, and apparently some elevation of temperature, though he was unprovided with a thermometer and could not determine the degree of fever.

Animals, such as horses, dogs, pack-mules, etc., born in the lowlands, suffer in the same way as men when taken up the mountains, but animals born at high elevations are exempt. The native mountaineers are likewise untroubled by the malady, and can run, hunt, and labor hard in other ways at heights at which new-comers are utterly prostrated and incapable of the slightest muscular effort. Shepherds are found grazing their flocks in perfect contentment, both in the Andes and in the Himalayas, at elevations of about 16,000 feet, but they can seldom remain for any length of time at much greater elevations than this. The loftiest inhabited spot on the globe is said to be the Buddhist convent of Hanle, in Thibet, which is situated at an elevation of 16,533 feet. Here twenty priests pass their time in prayer and meditation. It is true, this occupation cannot be regarded as, physically, a very exhausting one, yet it must have required heavy labor to build the convent, and it would be interesting to learn the medical history of the laborers employed in its construction. The highest point in the Himalaya Mountains at which exercise was possible, was found by the Schlagintweit Brothers ("Reisen in Indien und Hoch-Asien") to be 21,982 feet. In the case of pack-mules driven beyond their powers, death from mountain sickness is not very unusual, and the malady has been known to result in death even in men, who were unused to mountain climbing, and who persisted in their upward struggles until the heart gave way under the unaccustomed strain. It is said that cats invariably die in convulsions if taken up much beyond 13,000 feet.

Alpine climbers seldom suffer acutely from mountain sickness, probably because they make graduated ascents, not often going to very great heights on their first trial. And, as was mentioned above, old and experienced climbers seldom experience any disagreeable symptoms, unless they have been living a long time on the plains, or happen to be run down by fasting, cold, or extraordinary fatigue. De Saussure, however, in an account of an

ascent of Mont Blanc in August, 1787 (" Voyage dans les Alpes "), says that the guides suffered severely, when attempting to put up the tent in which they were to pass the night, at the comparatively slight elevation of 12,763 feet. He himself suffered not a little from shortness of breath, weakness of the legs, and vertigo, but the distressing symptoms disappeared almost entirely when he turned so as to face the strong north wind, swallowing it, as he said, in great gulps.

M. Charles Martins made an ascent to the summit of Mont Blanc in July, 1844, going from Chamounix to the Grand Plateau three times. The third time he reached this point his guides had an experience similar to that of De Saussure's guides, half a century before, suffering quite severely from dyspnœa and weakness while engaged in shovelling away the snow in order to clear a space for the erection of the tent. Yet these same men had suffered no inconvenience of consequence in their two previous trips to the same spot. The reason why they were attacked more severely the third time was doubtless, as M. Martins says, because they had made the ascent with unusual rapidity. Dr. Auguste Lepileur, who accompanied M. Martins in this ascent, has described the physiological effects of the trip upon himself and the others of the party in an article in the *Revue Médicale* for 1845.

In August, 1869, Dr. L. Lortet, of Lyons, made two ascents of Mont Blanc, with the special object of studying the phenomena of the *mal des montagnes*. The first trip was made with a party of five, exclusive of the guides. The first night was passed at an elevation of about 10,000 feet. No special symptoms were noted at this station, except that M. Lortet had most pronounced anorexia and was unable to swallow a morsel of food. The first suffering was experienced after the party had ascended above 12,800 feet, the symptoms then complained of consisting of drowsiness, intense occipital headache, thirst, and dryness of the throat, complete loss of appetite, and nausea but no vomiting. In some of those examined the pulse ran up to from 160 to 172 per minute. There was a wretched feeling of malaise, and the sufferer had a sense of utter indifference concerning his own fate or that of his companions, very similar to the apathy of the sea-sick. On arriving at the summit this malaise passed away, but there was still shortness of breath and palpitation on the slightest movement. One of the party, who had not previously suffered, was taken suddenly, on arriving at the summit, with giddiness and vomiting of mucus and bile, which did not cease until the level of the Grand Plateau was again reached.

On the occasion of the second ascent, a few days after the first, M. Lortet felt only great drowsiness, but even this passed away under the stimulus of the cold wind, and of the snow beating against his face. He had no malaise during the trip, and could now eat with relish, having no return of the anorexia of the first ascent; but his shortness of breath was extreme.

An analysis of the symptoms manifested by the various members of the party developed some rather curious facts, especially in regard to the body temperature. Dr. Lortet made a number of observations on this point, and found that during the violent exercise of climbing, when near the summit of the mountain, the sublingual temperature fell in a remarkable manner. While sitting quietly the temperature was normal or nearly so (36.3° to 37° C. = 97.3° to 98.6° F.), but after a period of severe exercise it was greatly reduced, falling in one instance to a fraction below 32° C. (89.5° F.)! After a few minutes of rest the mercury again indicated a normal temperature. The writer remarks in support of the correctness of these remarkable findings, that subsequent experiments showed that violent exercise would reduce the temperature of the body from three-tenths to seven-tenths of a degree centigrade (one-half to one degree Fahrenheit), provided the individual were fasting. He explains the phenomena as follows: When a person in the lowlands exercises violently there is a transformation of heat into force, but by reason of the fact that a sufficient quantity of oxygen is available, the production of heat within the body keeps pace with its loss, so that the temperature is constantly maintained at the normal figure. In elevated regions, however, where the atmosphere is rarefied, the expenditure of force uses up the body temperature more rapidly than the organism can supply it. This loss of heat is further increased by the rapidity of the circulation, the blood not having time to become properly oxygenated while passing through the pulmonary capillaries. As the blood is also driven to the surface, it is probable that increased radiation aids in still further cooling the body. M. Lortet's explanation is quite ingenious, but not very plausible. A much simpler elucidation of the problem is that the reduction of temperature was only apparent, or rather that it was purely local. During exercise the members of the party were forced to breathe through the mouth and thus the parts were cooled off; after resting for a while the mouth could be closed, and then its temperature rose again to that of the body. The writer has repeated M. Lortet's experiment of exercising in the open air at a moderate elevation, actively and even violently, while fasting, and he has never found any appreciable reduction of the sublingual temperature as long as the mouth was kept closed.

The author of these observations was, however, so impressed with the startling fact of this reduction of temperature that he attributed the greater part of the phenomena of mountain sickness to it, although he was willing to concede that the vitiation of the blood by the accumulated carbonic acid might contribute to the results observed. He found that this loss of body heat did not take place in those who could eat regularly (possibly because these same ones who were able to eat suffered less from dyspnœa), and this observation afforded him an explanation of the utility of the guides' habit of eating every two or three hours. Unfortunately, he says, it is not usually possible to make use of this discovery in the way of prophylaxis, as the novice in mountain climbing has such an unconquerable repugnance to food that he finds himself unable to swallow a single morsel.

There are two other theories which have been advanced in explanation of the origin of mountain sickness. The more commonly accepted of these is that advocated by M. Paul Bert, who referred the production of the symptoms chiefly, if not entirely, to the diminished supply of oxygen. He believed that man ordinarily inhales more oxygen than he actually requires, just as he usually consumes more food than is absolutely necessary for the support of life; and just as one can accustom himself by degrees, and after more or less hunger and inconvenience, to a diet far below that which he ordinarily consumes, so he can gradually, at the expense of some dyspnœa and temporary suffering, habituate himself to dispense with this superfluity of oxygen. According to this theory the affection is due to the reduced oxygen pressure, as a result of which the red globules of the blood are able to absorb a smaller quantity of the gas than they do in the more condensed atmosphere of the lowlands. The process of acclimatization is accomplished by an increase in the number of the red globules, whereby larger amounts of oxygen, proportionately to the inspired air, are absorbed, little or none of the gas taken into the lungs being wasted, as it is in the case of individuals living at or near the sea-level. M. Bert examined the blood of the llama of the Andes, and found that it was capable of absorbing, for every one hundred volumes, at least five more volumes of oxygen than was the blood of sheep feeding in the plains. It has been shown also by Regnard and Müntz, in experiments upon rabbits, that a reduction of atmospheric pressure, either natural on mountains or artificial under a bell-glass, was followed by an increase of the hæmoglobin of the blood and a consequently greater power of absorption of oxygen.

The other theory is one advocated with much skill by Dr. Georg v. Liebig, who believes that mountain sickness is not essentially due to a diminished supply of oxygen in the air, but that it is rather a consequence of one's inability to breathe properly at first in a rarefied atmos-

phere. Similar symptoms, he says, are often observed under certain circumstances in the lowlands, as when one tramps, for example, in deep snow or in soft and yielding sand. In a person thus exerting himself one may see the veins swell and the face become purplish, his breath comes short and panting, his heart's action is labored and rapid, there may be even vertigo and momentary nausea, and he is forced to stop now and again as his legs refuse to do their duty. The origin of these symptoms is laid by v. Liebig to restricted respiration. As long as the severe exertion continues the abdominal muscles are tense and the belly is drawn in, the diaphragm is pushed up and cannot descend sufficiently to permit of full and deep inspiration, such as is needed to pump the blood out of the turgid veins into the right heart. The lungs also are more or less compressed, and while the bodily exertion creates a demand for an increased supply of oxygen, the impeded respiration permits of less being inhaled. The diminished supply results of course in imperfect oxygenation of the blood, and this in turn manifests itself in the muscular weakness, especially of the legs, and in vertigo and nausea. In this case the actual cause of the distress is to be found in the compressed position of the lungs, and although the malady is never so aggravated in the lowlands, disappearing always immediately upon the individual ceasing his exertion and resting, it is nevertheless the same in kind as mountain sickness. The origin of the ailment, in the one case as in the other, is to be referred to a disturbance of the respiratory function. In the lowlands the symptoms arise only upon great exertion, but at high altitudes they appear spontaneously or after moderate exercise and persist often even when the subject is at rest. In a rarefied atmosphere, v. Liebig claims, the lungs are compressed as a result of the diminished resistance to expiration, and full expansion is effected only by a conscious exertion. The result of this diminished respiratory power is seen in the gasps and hurried breathing, in the venous turgescence, and in the consequences of diminished oxygenation of the blood above detailed. Dr. v. Liebig therefore argues that it is to the change in the density of the air, rather than to the reduced quantity of oxygen contained in it, that the phenomena of mountain sickness are rightly to be attributed. He does not think that the hæmoglobin theory is sufficient to account satisfactorily for the facts of acclimatization, but holds that we can, in the course of time, so alter the rhythm of respiration as to accustom ourselves to breathe deeply and slowly, without being always conscious of the necessary expenditure of strength.

Neither of these theories seems to the writer to be sufficient in itself to explain satisfactorily all the phenomena of mountain sickness and all the facts of acclimatization. It would appear hardly probable, for example, that the absorptive power of the blood could have been so rapidly augmented, or that the respiratory rhythm could have been so quickly changed as to confer a practical immunity upon Mr. Whymper and his two companions after their single unpleasant experience. It is true that their former mountaineering may have brought about a permanent increase in the amount of their hæmoglobin, or that their past experience may have taught them to alter their respiratory rhythm unconsciously and rapidly to meet the necessities occasioned by the rarefied atmosphere; but in that case they ought not to have suffered so severely upon their first ascent of Chimborazo.

It is more easy to reconcile the second of these theories with the observed facts than the first, and it receives some support also in the writer's opinion from what has been observed in relation to sea-sickness. There are numerous points of resemblance between sea-sickness and mountain sickness, although in many respects they differ very greatly. One theory of sea-sickness is that the phenomena are the result of a disturbed respiratory rhythm, and a form of respiratory gymnastics has been proposed as an efficient mode of treatment for mild cases of the ailment. That the taking of prolonged and regular inspirations is useful in relieving a moderate amount of distress at sea, the writer can affirm from personal experience, though whether it would cure a pronounced attack of the malady he is inclined to doubt. The same procedure will relieve the first signs of mountain sickness also, but it may be permitted to doubt its efficacy in restoring a sufferer at fifteen thousand feet to his normal state.

It is most probable that both these factors—diminished pressure and lessened respiratory value of the air—are active in the production of the symptoms grouped under the name of mountain sickness, but it is possible also that there are certain meteorological or other conditions, impossible of detection by our present instruments of precision, upon the presence or absence of which variations in the intensity of the observed symptoms may largely depend.

The treatment of mountain sickness requires but brief notice. Rest is, of course, demanded, but even that is insufficient to bring relief in aggravated cases. No doubt deep and regular inspiratory efforts would be serviceable, but the immediate need for air is often so urgent that the sufferer can only gasp, and cannot be persuaded to take the time necessary for a prolonged inspiration. Oxygen would without question be of value for the relief of certain of the symptoms, whatever theory as to the causation of the malady may be correct, but ordinary mountain climbers are usually sufficiently encumbered with their necessary traps and cannot carry with them the apparatus necessary for making oxygen gas. Whymper made some trials of potassium chlorate, which might theoretically be thought useful in furnishing oxygen to the tissues, but his companions had an aversion to drugs and would not lend themselves readily to his experiments, so that it was impossible to determine what the effect of the remedy might be when given methodically and in proper dose. Fortunately, few people are called upon to ascend high mountains in the ordinary course of business, and those who do so from a love of adventure or ambition must make up their minds to take the unpleasant along with the agreeable. Of course, no one whose thoracic organs are not in perfect condition should ever attempt the ascent of a high mountain.

Thomas Lathrop Stedman.

LITERATURE.

The following are some of the more important works and journal articles on the subject of mountain sickness which have been consulted by the writer in the preparation of the preceding account of the malady:

Meyer-Ahrens, C.: Die Bergkrankheit, oder der Einfluss des Ersteigen grosser Höhen auf den thierischen Organismus. Leipzig, 1854.

Payot, A.: Du mal des montagnes considéré au point de vue de ses effets, de sa cause, et de son traitement. Paris, 1881.

Whymper, Edward: Travels among the Great Andes of the Equator. New York, 1892.

V. Liebig, Georg: Ueber die Bergkrankheit und Indicationen für Höhenkurorte bei Lungenleiden, Deutsche Medicinische Wochenschrift, 1880, vi., pp. 205 and 222. Die Bergkrankheit, Deutsche Medicinal-Zeitung, 1889, x., p. 305.

Lortet, L.: Deux Ascensions au Mont Blanc en 1869; Recherches Physiologiques sur le Mal des Montagnes, Lyon Medical, 1869, iii., p. 79.

Martins, Charles: Deux Ascensions au Mont Blanc, Revue des Deux Mondes, March 15, 1865.

MYELITIS. Little advance has been made during the last few years in our knowledge of this disease. Hayem and Parmentier have reported several cases of myelitis of blennorrhagic origin, but they are doubtful in character. Dufour also reported a case which developed during the course of gonorrhœa, and the autopsy showed characteristic lesions in the spinal cord, but no bacteriological examination was made.

Oppenheim has come to the conclusion that true primary myelitis is a rare disease. He says that a revision of the clinical histories of the hospital cases under his observation shows that the large majority belonged to the category of so-called compression myelitis (generally from disease of the spine, latent caries) or, as in two cases, from a malignant tumor of the abdomen extending to the spine. In some other cases post-mortem examination showed syphilitic disease of the spinal membranes, which extended to the cord. Very rarely a case which had been regarded during life as myelitis was proved to be a neurosis, especially hysteria. Frequently a case which was first looked upon as myelitis was

found, in view of its subsequent course, to be a disseminated sclerosis. A specially interesting case shows that a transverse myelitis may be simulated by a combined columnar disease:

A woman, fifty-one years of age, was admitted to the hospital on October 24, 1888. Since August, 1887, she had suffered from weakness and pains in the legs, with formication, and has been paralyzed for the last three months. During the last few weeks there have been flexion contracture of the legs, disturbances of the bladder, and a cincture feeling around the abdomen. At the present time she suffers from complete paraplegia with flexion contracture, increased tendon and cutaneous reflexes, diminished sensibility to touch and temperature, incontinence of urine; the upper limbs are normal. This condition remained unchanged except that the knee-jerk was subsequently lost. The case finally terminated fatally. The autopsy disclosed combined disease of the posterior columns, the lateral and anterior pyramid columns.

The diagnosis of chronic myelitis was also made very rarely (in four cases) by Oppenheim. When the cerebral symptoms were taken into consideration, the large majority of the cases were found to be disseminated or multiple cerebro-spinal sclerosis.

Oppenheim concedes that there is no longer any doubt of the intimate connection of disseminated myelitis (myelo encephalitis) with infectious and toxic processes. It may develop: 1, in acute infectious diseases (variola, scarlatina, typhoid, erysipelas, gonorrhœa); 2, on the basis of syphilis, tuberculosis and malaria; 3, in the puerperal state; and 4, in the cachexia due to the growth of malignant tumors.

Leyden divides the infectious diseases of the spinal cord into the following groups:

a. Parasitic diseases in which the pathogenic micro-organisms develop directly in the cord. Such cases are very rare. They include acute myelomeningitis which occurs as the result of typical cerebro-spinal meningitis. Leyden has shown that in some cases the diplococci enter the cord along the connective-tissue septa, and produce inflammation of the latter which extends to the white substance of the cord. Furthermore, capillary emboli appear in the cord as the result of ulcerative endocarditis, the latter being due to the presence of staphylococci or streptococci. It is also probable that acute poliomyelitis is an acute infectious disease, although the pathogenic micro-organism is still unknown. Spinal affections occurring in gonorrhœa are probably due to direct propagation of the gonorrhœal process to the cord.

b. Infectious myelitis due to the action of toxines formed during the infectious disease. One large group includes sequelæ of acute infectious diseases. They generally appear as disseminated myelitis with coincident affection of the medulla and pons. This variety also occurs after traumatism, and after pregnancy and childbed.

c. Toxic myelitis which occurs after the excessive ingestion of ergotin and spoiled maize, and in zinc workers (?).

d. Anæmic or cachectic myelitis. Lichtheim found under such conditions myelitic processes in the posterior and lateral columns of the cord, but they did not possess a systematic character.

The question with regard to the real nature of the so-called compression-myelitis of Pott's disease has not yet been definitely settled. The weight of evidence is in favor of the view that this condition is primarily a degeneration of the nerve-elements, due to the ischæmia which is consequent on the compression, but that at a later period an inflammatory condition develops in the degenerated parts. *Leopold Putzel.*

MYRTOL. A constituent part of the essential oil, derived by distillation, from the leaves of *myrtus communis*, L. It is supposed to closely resemble eucalyptol. It is a clear liquid with a powerful but not unpleasant aromatic odor. It is recommended as a disinfectant and deodorant, but has no bactericidal action. In medicine it is used to replace the balsams in bronchitis, blenorrhagia, and vaginitis. In small doses it improves the digestion and stimulates the appetite, but in larger doses it irritates the stomach. It is recommended particularly to remove the fetid sputum of bronchiectasis, and in gangrene of the lung. It is administered in doses of two to five minims, in capsules, repeated two or three times a day. *Beaumont Small.*

NAIRN. A Scotch sea-side resort of growing popularity. Nairn is a royal burgh of great antiquity, not far from Inverness, and pleasantly situated on the shore of the Moray Firth, at the mouth of the river Nairn.

It is a healthy place, with a fine sandy beach, and is popularly referred to as the "Brighton of the North." According to Black ("Watering-places of England, Scotland, and Ireland"), the climate of Nairn is "dry and bracing, and such is the influence of the sea on the air surrounding it that the extremes of temperature experienced at places more inland are not felt here. On no occasion during the last twenty-one years has the thermometer in the shade risen above 78.3° F., or fallen below 11.2° F. The annual mean temperature, calculated from a series of accurate observations, would seem to be 47.9° F.; that of summer (April to September), 54° F., and of winter (October to March), 41.8° F.; the difference between the means of these two seasons being 12.2° F. August, on an average, is the hottest month in the year, and February the coldest. The air is driest in June and dampest in February. The mean annual height of the barometer, corrected to 32° F., and reduced to the level of the sea, is 29.810 inches. The highest elevation of the mercurial column thus corrected, during twenty-one years' observation, has been 30.881 inches, and the least, 27.998 inches; the range of this instrument is smallest in June and greatest in November; the annual average does not exceed 1.408 inch. The yearly rainfall does not amount to more than twenty-six inches; the greatest quantity falls in October and the least in April."

Nairn has been recommended as a winter-resort, but it has no just title to be so considered, as the meteorological data just given amply demonstrate.

Edmund C. Wendt.

NAPHTHALENE. In addition to the external use of naphthalene in the treatment of parasitic and other forms of skin disease, and as an antiseptic dressing, it has been extensively employed as an internal remedy in all conditions in which an intestinal antiseptic is indicated. Its insolubility makes it a very safe medicine, and enables its antiseptic action to be continued throughout the whole course of the intestinal canal. Professor Rossbach, of Jena, first employed naphthalene in acute and chronic intestinal catarrh, and its use has been extended to cholera infantum, summer diarrhœas of children, dysentery, and all forms of dyspepsia and intestinal indigestion, accompanied by flatulency and fermentative changes. It is given in doses of 2 to 6 grains to children, and from 15 to 20 grains to adults, repeated three or four times a day, its administration being preceded by a dose of castor-oil. Some have obtained good results in infants by giving it in ¾-grain doses every two hours. To adults it has been given in as much as 60 to 90 grains in the day. It has also been used as suppositories, 15 grains of naphthalene to 2½ drachms of cacao-butter, introduced after an evacuation. It has proved of service in dysentery and in ulceration of the rectum when introduced as an enema: naphthalene, 5 parts, olive-oil, 200 parts. This may be introduced by means of an ordinary syringe, and repeated three or four times a day if required.

Naphthalene has also been highly spoken of as an antiseptic for the treatment of typhoid fever. Its advocates claim for it a decided beneficial action in shortening the duration of the fever, a lessening of unfavorable symptoms and complications, and a lowering of the death-rate. Dr. L. Wolff reported (*Philadelphia Medical News*, May 23, 1891) a series of one hundred cases, with a mortality of only two per cent., excluding certain deaths from causes outside the fever, and a mean duration of the fever of

24.3 days. On admission calomel and soda was administered to empty the intestine, and this was followed by five grains of naphthalene every four hours, alternated with a few drops of hydrochloric acid; no other medication was permitted excepting chemical antipyretics and cold sponging for hyperpyrexia. Dr. Wolff found that although it has no direct effect in lowering the temperature, its continued use speedily produced lysis and a normal temperature; in cases in which it was at once discontinued the temperature rose again. It was found necessary to continue the drug for some time after the temperature became normal. He considered that at the onset of typhoid fever naphthalene may inhibit the development of the pathogenic microbes, so far that the disease could be aborted; and that at any period in the disease over-production of the chemical toxines may be prevented, and the fever made to run a mild course. Naphthalene has been widely employed in hospital and private practice, and still receives its share of attention with other intestinal antiseptics. The results of this treatment, however, has not been uniformly favorable, and this, together with its disagreeable odor and taste, has proved a decided disadvantage and tended to lessen its employment. Other antiseptics without these disadvantages, notably salol, have replaced it to a great extent.

Naphthalene has been recommended as an anthelmintic by Dr. Mirowicz (*The Lancet*, December, 1891). He considers it superior to all other remedies on account of the certainty of its action and the absence of all toxic effects. It has proved of service against all kinds of intestinal worms, and its action is prompt and effective. One dose has caused the expulsion of a tape-worm, the head included, and in thread-worms and ascarides it has proved equally beneficial. Previous to administering the drug the patient should be dieted with salted, acid, and spiced foods. It should be given on an empty stomach, and followed by a dose of castor-oil. The quantity for adults is from 8 to 20 grains; a dose of 15 grains has usually proved sufficient; children may be given from 4 to 8 grains. It has also been used as an injection for pin-worms, the drug being mixed with one and a half to two ounces of olive-oil.

The fumes of naphthalene have been employed with some success in whooping-cough. A small quantity is to be placed in a dish and surrounded with hot coals; it soon melts and fills the room with white fumes. To be effective the patient should inhale the fumes continuously until the cure is complete.

The disagreeable taste requires it to be given in capsules or rice-paper, or in pill form. It may be formed into pills by mixing with half its weight of powdered marsh-mallow root and forming into a mass with mucilage. When given as a powder it may be mixed with sugar, and its taste and smell disguised by a drop of oil of bergamot or peppermint. *Beaumont Small.*

NAPHTHOL CAMPHOR. CAMPHORATED NAPHTHOL.—The preparations and derivatives of naphthol, such as betol, beta-naphthol-benzoate, and microcidin, have in a great measure supplanted the drug itself, both for internal and external use. The combination of naphthol and camphor, although known for some time, has recently been recommended for the treatment of tuberculous glands, tubercular phthisis, diphtheria, and as a valuable antiseptic wherever such is indicated.

It is prepared by rubbing together one part of beta-naphthol and two parts of powdered camphor. A viscid liquid results, insoluble in water, but freely miscible with oils. It should be kept in well-stoppered, dark-colored bottles, as it readily decomposes when exposed to air and light.

Dr. Jules Reboul, of Marseilles, who advises its use in tuberculous glands, employs it by injecting eight drops directly into the gland tissue, and repeats the injection every second day. Should any matter have formed, it is first to be evacuated. In cases where the gland has been laid bare by ulceration, a tampon saturated with the naphthol camphor and placed in contact with the surface has produced a healing action, not only in the gland itself, but also in the other affected glands in the neighborhood. The drug is absorbed and produces a beneficial action, both local and general in character. Its effect is prolonged, and the drug can be detected in the urine for twenty-four hours after an injection. The treatment is absolutely harmless and simple. In forty-seven cases reported by M. Reboul, twenty-eight were said to be cured and nineteen improved. It was also used in cases of tuberculous disease of the testicles with equal success. He injected four or five drops every eight or ten days into the tuberculous nodules on the epididymis and testes. In tuberculous disease of the lungs it is employed by being injected directly into the parenchymatous tissue of the affected lung, two minims in two and a half drachms of olive-oil being used.

As a local antiseptic it is said to be most active and effective. In diphtheria it has proved of much benefit, as it removes the false membrane and leaves a healthy healing surface. When applied to mucous surfaces it is frequently accompanied by pain, and requires an application of cocaine previous to its use. *Beaumont Small.*

NARCOSIS, FROM ADMINISTRATION OF ANÆSTHETICS. It is not the purpose of this brief article to trench on the broad field covered by the subject "Anæsthetics," in this volume, nor to attempt to improve upon work there so ably done. Simply, in as practical and concise a way as possible, the writer will herein group, from the stand-point of clinical surgery, those methods of treatment of anæsthesia-narcosis in excess which seem to him valuable, beyond a peradventure; and which should be clearly formulated in the mind of every operator. Other modes of treatment, such as by electricity and by means of various drugs, of secondary or doubtful value, will not be touched upon.

This accident is so appalling when actually at hand, and demands so cool a head and such instant resource, that no apology seems necessary for devoting to it a special, though short, chapter in this work.

Following the teaching of Dr. H. C. Wood,[1] in his recently repeated experiments, we agree that the treatment of both ether and chloroform narcosis should be identical. And, while in experiments on dogs the respiration often seems first and chiefly at fault, experienced anæsthetizers know that the heart (at least in the human subject) often gives as early—sometimes earlier—warning of threatened failure. This is especially true of chloroform narcosis; and with either drug it behooves a careful operator to put an experienced man on guard, and not the usual tyro; and to see that both pulse and respiration are watched ceaselessly.

It is, of course, best to *prevent* the peril under discussion, if possible; and the writer firmly believes that with this idea in view it is always wise to administer, about fifteen minutes before the anæsthetic, as large a hypodermatic injection of morphine, guarded by atropine, as seems safe. For instance, gr. $\frac{1}{4}$ to $\frac{1}{3}$ morphine sulphate, and gr. $\frac{1}{120}$ atropine sulphate, in an adult.

The reasons for this course are elsewhere fully discussed (see Anæsthetics); one alone should be enough to determine the question, namely, that under this treatment much less of the anæsthetic is needed in order to keep the patient "under to the surgical degree." Consequently the dose of ether or chloroform being considerably lessened, the liability to poisoning is proportionally diminished. And incidentally it may be added, both morphine and atropine are agents of value to ward off shock due to the operation.

Because of its great value as both a respiratory stimulant and a heart tonic, and for the reason named in the last sentence, the writer approves of the use for a day or two, in moderate doses, prior to any severe operation, of *strychnine sulphate*. Perhaps, when shock is actually present, it is of more value, if pushed to moderate strychnization, than any other single drug; and if this be true, its use in *prevention* of that shock when anticipated would seem sensible.

As Dr. H. C. Wood has demonstrated,[1] it is of decided value when used by needle during anæsthesia-narcosis;

and here again its use in prevention seems occasionally indicated.

An ounce or two of whiskey or brandy, before the anæsthesia is begun, can have none but a beneficial effect; of this the writer is convinced. Being itself (in moderation) a cardiac stimulant, the alcohol is a safe addition to our narcosis; and, as is the case with morphine, will, though to a lesser extent, render unnecessary so large a dose of the anæsthetic as otherwise would be needed. But, during the operation, should excessive narcosis supervene—with or without the preliminary use of alcohol—*then* the writer can but agree with Dr. Wood in thinking that alcohol as a remedial measure would be folly, since it is a narcotic, and the patient is already suffering from too much narcosis. There are better systemic stimulants at hand which are not narcotics.

"Nothing can be more prone to produce fatal syncope than the commencement of the operation before complete anæsthesia has been induced; for here we have a lowering of the vital functions caused by chloroform, and the shock of cutting the skin, especially over a sensitive area, communicated along sensory nerves whose conduction is not yet in abeyance. Records of death under these circumstances (incomplete anæsthesia) show how often the fatality arises in cases where trivial, although painful, operations, such as reduction of dislocated limbs, circumcision, etc., are performed."[2]

Finally, under this heading (*prevention* of dangerous narcosis) let us discuss a plan little advocated in print, but which has only to be heard to commend itself; namely, as a measure of precaution in a patient of feeble vitality about to be subjected to operation, *maintaining a reserve-guard of pure blood*, by accumulating this in one or more extremities; to be released, however, in case of need from narcosis.*

Of course, accumulation of blood in this way in the members is not a new thing at all; but the *purpose* for which it is herein advocated is so, it would seem.

Dr. A. C. Post, of New York, was, I think, the first to use this device in anæsthesia. Dr. Charles McBurney read a paper before the New York Surgical Society, about a year ago, speaking of the plan as one neglected and worthy of more frequent use. He demonstrated it there and then upon a man brought for that purpose. The technique as described by Dr. McBurney was as follows: "Immediately before anæsthesia is begun an ordinary Esmarch bandage has been placed on each arm and thigh, close to the trunk, and sufficiently tight to obstruct the venous return. The radial and posterior tibial arteries have been carefully watched, and only when the limbs have become loaded with blood (distinctly swollen) has the constriction been increased to such an extent that all circulation, arterial as well as venous, has ceased in the limbs. Anæsthesia is then begun, ether having been used by me in every case, and the inhaler being an ordinary one made of muslin and paper, and containing a little cotton. The storage of blood in the limbs has not affected the patient's facial appearance at all, and no peculiar sensation has been mentioned excepting a little complaint in one or two instances regarding the bands. The method has been applied to ten operative cases (and many more since this paper was written). At the beginning of the anæsthesia from one to two ounces of ether have been poured into the inhaler from a measuring-glass. The patients have been remarkably free from signs of irritation; that is, congestion of the face has not occurred, and struggling has been nearly entirely absent. Complete anæsthesia, so that the conjunctiva could be freely handled, has been accomplished in from three to five minutes. Coughing has occurred only once, and then for a very short time. Trembling of the limbs has not occurred at all.

"The mouth has required wiping free from mucus only once. No mucous râles in trachea or bronchi have been heard in any case. During the operation the anæsthesia has been quieter and more perfect than is at all common with ether. . . . As soon as the operation has been terminated and the dressings applied, the bands have been removed, and all four limbs raised. The rapidity with which patients have recovered from the effects of the anæsthetic has been very noticeable. Most of them have been able to talk intelligently and answer questions correctly within three minutes. Vomiting has occurred but once, and then to a slight degree only. None of the usual stupor has been noticed after the ether-cone has been removed."

The purposes for which this device has heretofore been advocated are the relief of kidney and other overburdened emunctories, especially when these show signs of disease; speed of anæsthesia and of waking therefrom; less bleeding, during operations upon the head or trunk; avoidance of deleterious effect of the anæsthetic upon more blood than is absolutely necessary; shortening the period of bronchial and pulmonary irritation, which lasts until all the ether has escaped from the system; prevention of vomiting; and economy of anæsthetic.

To these should now be added Dr. Webster's suggestion, which the writer has several times made use of practically when feebleness of the patient has made him fear anæsthesia-narcosis. Not all four limbs, as just described, but for this purpose one thigh will suffice. This is corded at the groin, at first slightly, permitting it to swell with accumulated blood, and then tightly enough to obstruct all flow in either direction. The limb should now be kept wrapped in a blanket, with warm bottles or bricks about it. In case of dangerous narcosis, release the band, elevate, and pour the great quantities of pure blood contained in the limb into the body surcharged with ether or chloroform. The good result of this needs no discussion. Of course the other and more usual plans of treatment are also to be used.

Treatment of Narcosis.—Where respiration is mainly at fault, the heart being safe, Sylvester's method of artificial respiration is our best treatment, beginning always, as in drowning, by the expulsive effort. The passage-way to the larynx must be kept free from blood, mucus, and vomited matters; and either the tongue kept drawn well forward by a clamp on it (the mouth, meanwhile, being held open by a cork between the teeth, or any of the ordinary gags), or else Mr. Benjamin Howard's plan of raising the epiglottis should be employed, which is efficient if the nasal respiratory area is unobstructed. This latter plan is to over-extend the head as far as possible. The mouth is closed, and "a chain of three links" is made tense by this position; *i.e.*, the genio-hyoid muscles, the hyoid bone, and the hyo-epiglottic ligaments. Consequently the epiglottis cannot fall over the entrance to the larynx, and the air passes in freely through the nose.

Protrusion of the symphysis menti by the thumbs behind the rami of the jaw, is a plan often followed, in order to prevent obstruction of the larynx by the base of the tongue. The genio-hyo-glossi muscles are thereby drawn forward, in turn the glossi-epiglottic attachments are made tense, and the epiglottis thus lifted.

Koenig's plan, suggested in chloroform narcosis, is intermittent pressure upon the chest, one of the thumbs being placed in a space over the heart (differing simply in this latter respect from Nussbaum's method) between the apex-beat and the sternum. And Maas' modification of this plan is one whereby the pressure aforesaid is made very rapidly—one hundred and twenty times per minute. Both, it would seem, must act mainly by frequent expulsion of narcotized air, and admission of fresh; and consequently must come under this heading—artificial respiration. It is difficult to conceive that the thumb in an intercostal space over the heart can compress that organ appreciably or enough to excite it afresh to work, though we cannot deny the possibility.

Inversion of the Patient.—This, the plan of Nélaton, is generally regarded as our first choice when the heart is

* Dr. W. T. Aikens and Dr. L. M. Sweetnam, of Toronto, and Dr. Leonard Corning, of New York, have also all used and advocated this plan of sequestration of blood; but not for the purpose mentioned by the writer of this article. He has not heard of its actual employment by others beside himself, in prevention of dangerous narcosis. The credit of the suggestion belongs, however, with Dr. David Webster, of New York, who, as the writer finds, published a note upon it in the New York Medical Journal for October 29, 1887.

mainly at fault, although artificial respiration also aids a flagging heart. Dr. Chisholm, of Baltimore, depends exclusively upon this; and although his extensive record of operations under chloroform (ten thousand) without a death certainly makes his opinion deserving of respect, I think there are few who will, with him, refuse to use artificial respiration and other valuable aids to resuscitation in addition to inverting the patient.

The latter, upon the appearance of signs of suspended animation with failing heart, should be held from sliding off the table, which is meanwhile so tipped that the patient's head is downward, and almost vertical.

It has been taught that cerebral anæmia is hereby overcome through gravity, and, consequently, the nerve-centres controlling heart and respiration being better supplied with blood are enabled thereby to do more efficient work. To the writer it seems that this explanation is far from the true one. In only one way can blood from the lower part of the chest, the abdomen, and lower extremities, reach the brain, if the patient be inverted; *i.e.*, by being pumped through the heart. Certainly *not* by gravity alone. And since we know that mechanical distention of the chambers of the heart by the circulating fluid is a most important factor in exciting cardiac contractions, the proper explanation is not far to seek.

Rapidly repeated compressions of the chest, with both the surgeon's hands, in its lower—epigastric—portion, meanwhile, will aid expulsion of narcotized air; and following each such emptying of the lungs by the surgeon, the Nélaton posture (by dragging on the pectoral muscles through the weight of the arms hanging by the sides of the patient's head) causes a mechanical inspiratory act after Sylvester's principle. So that if the patient be held sufficiently inverted, this position, with Nussbaum's treatment (just mentioned) will render Sylvester's needless.

The writer prefers this combined method (Nélaton-Nussbaum) to Sylvester's, where both heart and respiration are failing; and this is certainly the rule rather than the exception.

Heat.—It cannot be questioned that among methods of exciting a narcotized heart to resume work, one of the most efficient is *heat*. A quart of hot water injected by syringe into the rectum, while the patient is inverted as just described, is standard treatment. The patient's body and limbs should not be left unclothed to be chilled, but should be wrapped in warm blankets. The late Dr. Sands, of New York, has stated that he valued most highly moist heat over the heart. The writer has seen not only this gentleman, but others of the best-known surgeons in New York, cause a blister several inches square on the præcordium by application of steaming hot cloths during daugerous anæsthesia-narcosis.

Dr. Charles McBurney has recently said in a letter to the writer, "When the heart flags seriously in ether and chloroform narcosis, I regard very hot applications directly over the heart as of decided value as a means of stimulating that organ to renewed activity. . . . I like the idea of your arterial saline injections very much, and shall use it at the first opportunity."

The latter sentence has reference to a plan, devised by the writer, whereby heat may, with infinitely more directness and efficiency, be brought to bear on the heart. This is, *to pump hot salt-water directly into the blood-current*, and thereby stimulate both heart and respiratory centre in the medulla.

This is so self-evidently a useful proposition as hardly to need argument in its defence. The wonder is that it was not long ago used for this purpose; but, so far as the writer can discover, it has not heretofore been suggested.

If, as is generally admitted, heat applied over the heart can stimulate that viscus—whether directly, by extension through the chest-wall until felt by the apex-beat, or reflexly—how much more efficient must be that stimulation when that heat is brought into the heart-chambers, in the circulating fluid!

The temperature of the salt-water used should be *as hot as the hand can possibly support*. This will be 49° C. (120° F.) or a trifle less; and therefore the thermometer need not be employed. A much higher degree of heat than this could safely be used; since globulin only coagulates at 70° C.[3] (158° F.), and serum-albumin at 72° C.[4] (162° F.); or about 40° F. hotter than the hand can bear. At the temperature first mentioned (120° F.) the writer has recorded[5] a number of cases of hæmorrhage so treated, with excellent results; and Dr. Edwin Sternberg, of New York, two more, with recovery; whereas others which he had treated also by saline infusion, but at bodily temperature, died.

It is demonstrated both by the writer's kymographic experiments, heretofore reported, and by the foregoing cases, that very *hot* saline infusion is not only safe but best, in severe hæmorrhage; and the same is true in the matter under discussion—heart-failure in narcosis from anæsthesia.

The strength of the salt-solution * is that normal to the blood-serum; roughly, a heaped teaspoonful of chloride of sodium to the quart of sterilized water. It is fair to assume that every operating-room, even in a private house, has water ready at hand that has been boiled and is still hot. This, some table salt, a Davidson syringe, and a coarse hypodermatic needle or a cannula are all the equipment needed. Remove the tip from the syringe, replace it with the cannula-hilt, and tie the latter in place with a thread. Disinfect this apparatus by pumping boiling water through it.†

As to the amount of the solution to be used, perhaps a pint may be called an average. In a case immediately threatening death I should inject still more, and hotter. The method is also of use in yet another way—by bringing added pressure to bear upon the heart-chambers, just as with the inversion plan (Nélaton's).

In hæmorrhage or in shock threatening imminent death, the writer has urged, in recent publications, the injection of the hot infusion *directly into the femoral artery;* the aspirating needle (not as yet attached to the syringe) finding it readily where, under Poupart's ligament, it is large enough in calibre to carry a lead-pencil, and a bright-red drop of blood welling up in the needle proving the latter to be in place; upon which the syringe-end is tied on and the injection begun.‡

But here, in anæsthesia-narcosis, there is not a moment to waste. The hot salt-water should reach the heart, in considerable amount, very quickly; more quickly than the hypodermic needle would permit. It is better therefore to use the cannula, and while the assistant is attaching the base of this to the syringe-end, and filling both with the hot solution, the surgeon opens a vein at the bend of the elbow—or the internal saphenous over the inner malleolus, or any other vein of fair size; perhaps one in the operation-wound. Now the cannula is tied within this vessel and the injection given. In a properly equipped room the injection may be begun within a minute or two of the time it is determined upon.

Of course if the patient is able to swallow, hot drinks—for example, black coffee—or other hot stimulants (save alcoholic), are indicated.

Cold.—Although in the writer's opinion not so efficient as heat, the application of a piece of ice over the heart will sometimes reflexly excite more vigorous contractions; and similarly, ice within the rectum aids respiratory efforts.

Use of Drugs.—Our syringe and cannula are still in

* We must never omit the salt—it would be fatal to mix plain water with the blood, as this at once dissolves out the hæmoglobin from the blood-disks; whereas even so small an amount of salt as that named—six parts per thousand—renders it safe.

† Of course well-equipped surgeons will not have to waste precious minutes by these steps, which may well be taken before the beginning of an operation requiring anæsthesia.

‡ The only objection—a self-evident one—to this device, in hæmorrhage, is the hesitancy naturally felt to pierce so large an artery; and this should vanish when one reflects that the most prominent plan now used by surgeons for aneurisms so placed as to be inoperable by ligation, and yet threatening rupture, is that of Macewen, of Glasgow, which is needling, and in which long needles are thrust—a dozen or so—into the sac, and left for many hours, to cause thicker deposits on the walls; and this with benefit, as a rule.

If a diseased vessel can safely stand such treatment as this, it seems a mild inference that a sound artery can bear a single needle for a single half-hour. And such has been the writer's experience thus far.

place—the latter tied within a vein. Either mingled with the hot salt-water, or preceding it, or following it, we may use properly diluted *aqua ammoniæ*, a remedy of unquestioned value. The latter, strychnine, and digitalis comprise all the drugs recommended as of real use in this condition by Dr. H. C. Wood in his Berlin Report in 1890, who however did not experiment with strophanthus and many other heart-tonics. He says: "From fifteen to twenty-five minims of the aqua ammoniæ fortior, diluted with four times its bulk of water, should be thrown directly into a vein of the arm, and repeated in fifteen minutes if necessary."[6]

The same drug may be exhibited by inhalation, with some caution, as it is capable of causing violent local inflammation where used in excess. The only hypodermic abscess for which the writer has ever been personally responsible was caused by an injection of aqua ammoniæ—and not the *fortior*—in a case of opium narcosis; not injected into a vein but into the subcutaneous connective tissue of the thigh. A slough more than an inch across resulted.

Regarding *amyl nitrite*, it is certain from Burrall's clinical cases that it must be of some value, although Wood found it inefficient on dogs. Paralyzing as it does unstriped muscle everywhere, and consequently completely dilating the blood-vessels, it must inevitably diminish the resistance caused by vascular tone against which the heart has to work in pumping blood. If that tone be lost from *complete* narcosis, then it is plain that in such case, at such time, this drug would be almost useless, since its *direct* stimulant effect on the heart is but slight, and the rapid action of this organ under amyl nitrite is due mainly to depressing the inhibitory centres; to which, in complete narcosis, the heart could hardly be expected to respond vigorously.

Strychnine has already been discussed. Both as a heart tonic and as a respiratory stimulant it is of great value.

Regarding *digitalis*, the testimony is equally strong, so far as the heart is concerned. The writer carries regularly to his operations a solution of strychnine sulphate in equal parts of the tinctures of digitalis and strophanthus, and has repeatedly used this combination by hypodermatic needle with benefit.

Strophanthus alone he has not employed. However, since it is more rapid in action than is digitalis, has less tendency to contract arterioles than has the latter drug, and stimulates the heart vigorously and very much like digitalis, it is obviously indicated.

Two remaining devices the writer has never seen used; but he cannot doubt their value in absolutely desperate cases. This has been repeatedly demonstrated on the lower animals. One of these is mechanical stimulation of the heart by a long, slender needle passed through the anterior chest-wall;[7] and the other, introduction of a finger through a cut in the præcordium, thus permitting intermittent pressure on the heart; to be repeated some twenty times, at the rate of seventy to eighty times a minute. It is not necessary to empty the heart thereby; a slight pressure will drive on some blood.[8]

In conclusion, it is perhaps needless to say that surgeons employ not one but as many as are deemed wise, at once, from this list of weapons against an enemy that comes unexpectedly and kills quickly if at all. Every moment is golden, and indecision or unwise choice may, in a matter like this, cost a life.

Robert H. M. Dawbarn.

NASAL SURGERY, ASEPTIC AND ANTISEPTIC.

The only reason why antiseptic methods have been employed so little in nasal surgery is because surgical operations in the nose have become frequent only within the last few years. It requires a few years for any line of surgery to develop antiseptic methods. In a very short time it is safe to predict that the rhinologist will be as particular in his methods of operating as is the abdominal surgeon of to-day. It would seem that either the general surgeon is over-careful in his attempts to secure perfect cleanliness, and over-zealous in the employment of aseptic and antiseptic agents, or nasal surgeons, so far as my knowledge extends, have paid too little attention to this matter of antisepsis in their operative work. If the germ theory of infection or of putrefactive fermentation of Pasteur, Koch, Lister, and Watson Cheyne—a theory which is firmly believed in by nine-tenths of the leading American surgeons to-day—if this germ theory is proven, nasal surgeons need to be as particular as other surgeons in their methods of operating.

In a discussion of a paper by the writer, entitled "Antiseptic Nasal Surgery," by the American Laryngological Association, at its Tenth Annual Congress, 1888, various opinions were expressed as to the necessity of employing antiseptic measures when doing nasal surgery. The discussion became very general. Several of the gentlemen said they did but little nasal surgery, because in their opinion there were but few cases that required surgical interference. A small number employed only the galvano-cautery in removing tissue, and were not favorably disposed toward cutting and drilling operations upon the bony and cartilaginous structures of the nose, so that, aside from the observance of strict cleanliness in treating nasal disease, they had had but little occasion to employ antiseptic solutions. I would like to add, in parentheses, here—and I shall refer to it again—that the application of the galvano- (that is, the actual) cautery to open wounds affords one of the most effective means of preventing the absorption of septic material. Gerster[1] says "the actual cautery is the most effective sterilizer." It may be true, therefore, that if only the galvano-cautery is used in removing nasal obstructions there is little need to employ other antiseptic precautions. Strict cleanliness before operations, and application of the actual cautery to the wound would perhaps satisfy most aseptic operators. While it is true, however, that the majority of rhinologists do make use of the saw, scissors, and trephine, so short a time has elapsed since these instruments were perfected, and also, indeed, since nasal surgery has assumed its present large proportions, that it is perhaps still too early to pass judgment upon the question whether perfect asepsis and antisepsis are attainable in nasal surgery.

A second reason for the lack of attention paid to the use of antiseptics in nasal surgery is that the wounds inflicted by operations are very small as compared with those which the general surgeon has to treat; but the advantage the nasal operator possesses in the loss of a smaller extent of surface tissue is more than equalized by the peculiar conditions of nasal wounds, and these conditions furnish the *third* reason why antiseptics have been held at so low a value by nasal surgeons. It is far more difficult to employ antiseptic methods effectively in the nasal cavities than upon the surface of the body or in the abdominal or pelvic cavities. Not only is it wellnigh impossible to obtain an aseptic condition before operations, as can be done on the surface of the body, by thoroughly scrubbing with soap and water, and sponging with a solution of carbolic acid or bichloride of mercury, but the nasal wound is subjected to all the conditions which are deemed most favorable to the generation and propagation of micro-organisms, viz., heat and an abundance of moisture and oxygen.

Watson Cheyne[2] says: "The ideal result of wound treatment is seen in the repair of subcutaneous injuries." He might have cited nasal wounds as the most unfavorable illustration of wound healing. The decomposing nasal secretions add to the fertility of the soil which is most favorable to the development of pathogenetic microbes. The swelling of the tissues within the bony nasal walls prevents effective drainage, one of the safeguards against septic absorption, and the pent-up secretions furnish ample septic material until the absorbents are satisfied. We find, therefore, in nasal wounds

caused by operation both varieties of the "obstacles to repair" which are recognized by writers—the mechanical and the chemical. The mechanical are present in the particles of bone, cartilage, or soft tissue, or in the atoms of dirt which remain in the nasal cavities unless great care is taken to wash them out, while all the usual conditions of nasal wounds favor putrefactive fermentation, which is the basis of the chemical obstacle to healing.

In endeavoring to mention all the difficulties lying in the way of the practice of aseptic nasal surgery, we must not forget that the peculiar anatomical structure of the nasal tissues and the peculiar physiological function they perform, furnish additional hindrances to the proper treatment of wounds. If an attempt is made to exclude all air from an ulceration on the septum, by covering it with a protective and sealing the nasal orifice, we have the evil results which are caused by the irritation of these packings in the nostril. The erectile tissues will not bear the contact of a foreign body with impunity, the dressings disturb the vaso-motor reflexes, and the nostrils are filled with mucus and serum, which wet the dressings and render them less effective.

In view of these difficulties the question may be asked, Is it possible to obtain an absolutely aseptic condition for the healing of nasal wounds? We think not. If this is true, is it the duty of the nasal surgeon to use all antiseptic methods possible? Are we depriving our patients of any degree of safety or comfort by treating nasal wounds as the general surgeons treated all wounds before antisepties were known? To make the question still more tangible: Do we see symptoms of septicæmia more frequently following those nasal operations where no antiseptic precautions are observed, than those which are protected by every effort to exclude disease-bearing germs? Our experience would say, yes, emphatically. We believe that few patients would die if nasal wounds were made with unclean instruments; but everyone is entitled to every safeguard which protects his life, and which adds to his comfort. Our patient must not be put to bed because of a small nasal operation. It is possible to do nasal surgery in such a manner that his business will not be interfered with. I shall not at this time discuss the point whether there is more surgical work performed in the nose than is requisite or judicious. There should be no debatable ground as to *how* it should be performed.

In 1888, before antiseptics were generally employed, when investigating the value of antiseptic methods in nasal surgery, I found that it was almost the universal testimony of those who used the knife, the saw, the scissors, and the trephine, that constitutional disturbance, more or less marked in character according to the amount of tissue removed or the extent of surface denuded, followed a certain percentage of these operations. These symptoms may be stated as commencing in from twelve to forty-eight hours, with slight chilly feelings, occasionally with a chill, and followed by a rise of temperature ranging from 99.5° F. in mild cases, to 103° F. in severe ones, headache, pains through the eyes, nose, and forehead, and in the back and limbs. The patient feels too ill to engage in any business. Men of nervous temperament remain at home for a day or two, and women stay in bed. These patients seem to be extremely nervous and irritable, and they do not thoroughly regain their equilibrium for some time. Some of the above symptoms occurred in some degree after, perhaps, twenty-five per cent. of the cutting, sawing, or drilling operations on the nose. Of the severe cases I have seen but one in my practice, and that was not in any sense grave. I may describe it.

In the spring of 1887 a young man came to me with his left nostril almost entirely stopped with cartilaginous deflection. I remember him as one of the most nervous patients I ever saw. The trephine driven by the electric motor was used. The operation lasted but a few moments. Hæmorrhage was not severe, but it was persistent, and I placed an ordinary cotton tampon against the wound. The patient came to the office the next day. I removed the plug and washed the nostril with a carbolized solution, but, as the bleeding continued, I put in a second tampon. I saw the patient at his house the next day. The tissues over the left nostril and cheek were swollen and red, the left eye was almost closed by œdema of the lids. The patient had had chilly feelings the night before, and I found his temperature 102.5° F. He exhibited the nervous irritability spoken of. I removed the plug and washed the nasal cavities with carbolized solutions. He began to improve the next day, and was about in four days. In another case, operated upon in 1886, after the use of the galvano-cautery on the septum, the patient suffered from constitutional symptoms; temperature, 101.5° F.; and on the second day after the operation an erysipelatous blush showed itself on the nose and for a short distance on the cheeks. This lasted only twenty-four hours and the patient quickly recovered.

I formerly saw numbers of cases where the patient felt uncomfortable the second day after an operation on the septum. There was probably some slight rise in temperature in all these cases. It used to be common enough in dispensary practice to have patients return a few days after a cautery or drilling operation on the nasal septum, and say that they had felt quite ill for some time after the operation.

My attention was most forcibly called to the serious results which may follow nasal operations by the uncomfortable experience of a prominent surgeon of New York. He was operated on by a physician of experience in nasal work. A cartilaginous and bony convexity of the septum was removed by a revolving drill The work was done under chloroform. The second day after the operation the nostril was closed by inflammatory swelling. The patient had a chill on the evening of the second day, and for seven days afterward the temperature ranged from 103° to 104° F.; slight chills were frequent, perspiration abundant, albumin in the urine. The nose, eyes, and face were considerably swollen. The patient lost flesh so rapidly and was so depressed mentally that fears were entertained at one time that he would not recover. He convalesced slowly, and was unfit for work for six weeks. In conversation with me about his case he criticised in strong language the lack of antiseptic methods employed by nasal surgeons. He himself, a strong advocate of all antiseptic precautions, and most particular in his practice as a general surgeon, styled the old-time methods by the more expressive than elegant term of "rotten surgery." There was no doubt but that he had suffered from a severe attack of blood-poisoning, the "septic intoxication" of Cheyne, the "traumatic infectious" disease of Koch. Absorption of putrid matter had taken place through the denuded cartilage and bone of the nose, and, as a consequence, he had almost lost his life. I have heard of other serious cases, but have no authentic history of them. But this all occurred from 1886 to 1888.

The constitutional symptoms which follow operations in the nasal cavities, even where no antiseptic precautions are resorted to, may not be severe nor long continued. The patient's life is rarely endangered, but his comfort may be seriously interfered with. There are a number of rhinologists who do not perform cutting or drilling operations upon the nose because they fear the constitutional disturbance that may follow such operations. As one physician expresses himself in regard to these operations, he "prefers to be on the safe side." Is it not possible to operate freely in any nasal case where good judgment advises, and, by employing strict antiseptic precautions, always be on the safe side?

General symptoms, which appear during the first twenty-four hours after a nasal operation, may properly be attributed to shock and the reaction after shock. The amount of shock will depend upon the temperament and general health of the patient. Sex seems to have little significance. Shock will be in proportion to the amount of tissue removed, the extent of surface laid bare, the amount of pain inflicted, and the quantity of blood lost. The degree of shock is also in direct ratio with the length

of time consumed in operation. Shock seems to be greater when the nasal septum is wounded than when the soft tissues are injured, but this perhaps is because the saw, scissors, or trephine are rarely used on soft tissues. All the symptoms which may be fairly attributable to shock following the small operations upon the nose should be over in twenty-four hours. For example, a cutting operation is performed upon the septum, and in a few hours the patient may feel generally shaken up—with headache, neuralgic pains about the eyes, nose, and teeth; he may feel weak and perhaps even faint; reaction declares itself in a slight rise of temperature, not more than 99.5° F., which subsides in twenty-four hours. We should not confound such constitutional disturbance with symptoms which begin later, last longer, and are more pronounced—symptoms which surgical writers formerly grouped under the names of "traumatic" or "surgical" fever.

The transitory disturbance called shock subsides as soon as the nervous system has had time to recover its equilibrium. But neither shock to the nervous reflexes nor mechanical disturbance of the nasal circulation is considered any longer competent to explain the systemic disturbance which was called "surgical fever" by the operators of twenty years ago. Thanks to the investigations of Pasteur and Koch, and to the antiseptic surgical procedures elaborated by Lister, traumatic fever is no longer a legitimate disease which follows all surgical operations. The presence of marked constitutional disturbance, chills, and high temperature after the severest operation now reflects unfavorably upon the methods employed by the operator, and the old "laudable" pus, teeming with germs of suppuration, has been proven to be an evidence of wound infection.

The belief that symptoms such as we have described were caused by the action of micro-organisms, and were not, as Billroth [3] has it, "the general accidental diseases which may accompany wounds," had been suggested at the beginning of this century; but, in 1831 Braconnet stated the opinion that micro-organisms produced virulent principles which acted as ferments. In 1836 Donne discovered microscopic organisms in the pus of chancres. In 1848 Fuchs spoke of the presence of bacteria in some of the septic diseases of animals, and Pollender, in 1850, discovered bacteria in the blood of cattle dying of charbon.

In 1861 Pasteur began his remarkable demonstrations, proving first that butyric fermentation was effected by an organism, and in the next year that there existed in the air countless organized corpuscles which were the germs of fermentation. In 1863 he stated that putrefaction was determined by ferments of the vibrio species. This theory of the relation of putrefaction to fermentation was quickly and naturally applied to pathological conditions, and the germ origin of splenic fever was soon demonstrated.

Pasteur was first to maintain that septicæmia was of germ origin. Koch has demonstrated, by inoculation in animals, that a number of diseases similar to those in men are caused by a specific microbe. Pathogenetic microbes have been demonstrated in erysipelas, gonorrhœa, anthrax, empyema, tuberculosis, osteomyelitis, etc. Rosenbach,[4] of Göttingen, after painstaking experimentation, denies the possibility of the formation of pus by mechanical, physical, or chemical means if microbes are excluded, and Ogston [5] has also quite clearly shown that all suppurative processes are caused by micro-organisms. Gottstein,[6] of Berlin, says that the microbes found in pus probably exist in a latent way on the skin, and in the mouth and nose, and become active only when a wound is produced which gives them access to the blood-tissues, or rather furnish an opportunity for the absorption of the *products* of the micro-organisms—the so-called ptomaïnes, or the sepsin of Bergmann, or the "putrefactive alkaloids," or the *excrementitous products* of the microbes mentioned by other writers. Gottstein further says that this absorption continues until an aggregation of leucocytes furnishes a barrier which prevents its further progress. This dam of leucocytes is the granulation tissue which is present in old ulcerations, and its presence explains why we have no symptoms of blood-poisoning in ulcerous coryza and other long-continued ulcerations of the nose. Gottstein asserts that these micro-organisms are the cause of traumatic infectious diseases. Cheyne [7] remarks: "The antiseptic method is based on the germ theory of fermentation and putrefaction, and not necessarily of infectious disease." Roswell Park [8] says: "The lowest forms of vegetable life are the cause of all forms of fermentation, only a certain number of which are putrefactive." This latter fact granted, antiseptic surgery has given its reason without discussing in detail the origin of surgical diseases. Some one has said that "antiseptics should be used to supplement cleanliness." Gerster [1] says in his text-book that "modern wound treatment is based entirely on the old and well-known principles of the preservation of organic substances." I cannot do better than to quote once more from Cheyne,[2] whose very intelligent writings make the subject of antiseptics a very attractive one. He says: "When a wound is large, and no antiseptics are used, absorption takes place, and we have in a few days *traumatic fever*, and that the symptoms of septic intoxication are due to the absorption from the wound is proved in that the symptoms subside when granulation takes place."

The bacteria which are found in the nostril may be harmful or harmless. Nature may or may not be able to prevent the entrance of septic germs through surgical wounds of the nose, or render them innocuous after their entrance. These considerations remain to be settled by bacteriological study, but the experience of some years in nasal surgery has fully satisfied us that our patients suffer far less after operation from constitutional disturbance, and the wounds heal more quickly, when they are somewhat protected from external influences. Dr. Jonathan Wright, of Brooklyn,[11] has made a careful study of the various kinds of bacteria which he found in the healthy nose, and if space allowed it would be of interest to quote largely from his article, "Nasal Bacteria in Health," but a few results must suffice. He found that the bacterial forms varied very much according to the dry or moist condition of the streets, and the amount of wind existing. The staphylococcus pyogenes was by far the most frequent variety found. The investigations of many workers in this field have demonstrated that this form of bacterial life is found upon all the mucous surfaces and upon different portions of the human body. Whether this particular germ is the one which is to be feared after nasal operations remains to be decided. The many conditions which are necessary to the growth of this, as well as to that of the many other forms of micro-organisms, leaves us in doubt as to the influence they exert upon a nasal wound. They must be in sufficiently large numbers to overcome Nature's resistance. Although the staphylococcus pyogenes is found in abundance in the mouth, it is a significant fact pointed out by Wright,[11] that infection never follows excision of the tonsils or uvula.

Nasal wounds, however, are apparently much more exposed to pathogenic organisms than are injuries of other mucous surfaces, for the nostrils filter them out of the inspired current of air, as has been proven by Aschenbrandt [13] and others. Wright conducted a series of experiments which showed that while ten litres of laboratory air contained four moulds and one hundred and twenty-five bacteria, it contained only one mould and twenty-four bacteria after its passage through the nose,

This is not the place to give the various opinions held by ardent students as to the manner in which nature renders the septic germs harmless, whenever they have obtained entrance into the circulation. It is enough for our purpose to state that the larger number of investigators believe that pathogenic germs are killed by the chemical action of the blood serum, while the minority, represented perhaps by Metschnikoff,[14] hold that the real enemy of disease-bearing bacteria are the leucocytes.

Those who argue against the value of using antiseptics in nasal surgery maintain that since it is impossible to

obtain anything like an aseptic condition of the nose, antiseptic precautions are almost valueless. They might as well say that since the nose cannot be made perfectly clean it is useless to employ any cleansing sprays whatsoever.

Were we ever so indifferent as to the importance of treating nasal wounds antiseptically, we cannot ignore the greatly improved results which surgeons have been able to obtain since they have employed antiseptic methods. The largest operations are so scientifically performed in our hospitals to-day that we have ceased to wonder when we observe that there is less constitutional disturbance after an exsection of the knee, an amputation of the thigh, or an abdominal section, than formerly followed the loss of a finger or toe. A most interesting paper was read at the New York Academy some years ago, which brought out an earnest discussion. The writer advocated external operation for deep urethral stricture on the ground that in performing internal urethrotomy proper drainage was obtained with great difficulty, and that urethral fever, the great bugbear of operators, was due to sepsis and not to nervous causes. The discussion was as to the causation of urethral fever. I believe only one surgeon who discussed the paper indorsed the older theory, that urethral fever was due to reflex nervous causes. In extirpation of the tongue it is found that there is much less danger of septicæmia where preliminary tracheotomy is done, and it is thus rendered possible to employ antiseptic solutions and to partially exclude air from the mouth.

There are two general methods of treating nasal wounds after operation, viz., the open and the closed methods. Among nasal surgeons of large experience there are strong advocates of each. Some operators believe that nasal wounds do well enough if left entirely alone. They do not fear infection, either from the germs which are habitually found in the healthy nostril, nor from those special micro-organisms characteristic of erysipelas, scarlet fever, etc. We should consider it unsafe to advocate such indifference to antiseptic methods. They claim that the blood-coagulum is ample protection against wound infection. There seems to us to be many disadvantages attending the "open" method of wound treatment, and 1st, the danger of hæmorrhage. Strong solutions of cocaine are always used in cutting operations in the nose, so that hæmorrhage immediately after the operation may be slight, for the reason that the cocaine has expelled the peripheral circulation. The bleeding ceases and the patient is allowed to go on the street. The circulation in the nose is restored after a little, and profuse bleeding from the uncovered nasal wound may take place, if not to the danger, at least to the discomfort, of the patient. 2d. If it is granted that there is no danger of infection from the ordinary germs that are commonly found in the nose and in the atmosphere, should we leave nasal wounds exposed to the germs of erysipelas, scarlet fever, diphtheria, etc. ? To dispensary patients such exposure must be common enough. 3d. We have found that nasal wounds heal more quickly when covered by some antiseptic protective.

We believe the majority of writers advocate some modification of the closed method of treatment after operation. We repeat what we have said before, that we think it is impossible to hermetically seal a nostril either by the method proposed by Kitchen[15] or the very similar one proposed by Roe.[16] This plan is to cover nasal wounds with flexible metal, such as tin, copper, or aluminium, the metal shield to be fitted accurately to the wound, after it has been covered with antiseptic cotton or gauze. Our experience with all such appliances is that they are very difficult to adjust, and that most people cannot, or will not, wear them, because of the pain and discomfort they produce. Dr. Roe calls this the "aseptic method as applied to intra-nasal surgery," because he claims that the metal covering entirely prevents the access of pathogenic germs to the wound.

A method advocated by Dr. L. Freudenthal, in a paper read before the Academy of Medicine, in November, 1892, seems to us to promise more encouraging results. He covers the wound with a specially thick collodion, and he expresses the hope that this obtains for the wounded surface an aseptic condition. We have had no experience with this method.

It is wise, we think, to follow some *routine method* in our attempts to secure as nearly as possible an aseptic condition of the nostrils and wound. The success of all antiseptic methods depends upon methodical detail. The methods which are advocated both before and after the operation are in no sense new, but I state them, because, as I have said, it is well to have a detailed routine. Something may be accomplished in the right direction if the patient is instructed to wash out his nostrils twice daily for some days before the operation, with a tepid saline or alkaline spray, such as a modification of Dobell's or Seiler's antiseptic tablets. I like a prescription of peroxide of hydrogen, twenty per cent., containing one per cent. of cocaine muriate in solution. The peroxide of hydrogen cleanses to better advantage after the swellings have been partially effaced by the cocaine. A solution of salt and water, generously and carefully used, does more than cleanse—it acts as an antiseptic. A solution of mercuric bichloride, 1 to 4,000, sprayed with an atomizer is beneficial, but is apt to be irritating. Freudenthal sprays with sterilized water. Tavel's fluid, composed of salt, seven and a half per cent., and natr. calc., two and a half per cent., is recommended on the ground that it is a physiological fluid. The operator can wash out the nose with some one of these solutions just before operating. A sterilized ten per cent. solution of cocaine may be applied to the portion of the nose to be operated upon. All instruments should be sterilized or placed in the usual carbolic surgical solution, and the hands of the operator made aseptic.

I am in the habit of covering the portion of the nostril to be operated upon with clean absorbent cotton, wet with a solution of mercuric bichloride, 1 to 2,000, after the cocaine has been applied, and just before operating. This cotton is only left in position for a moment or two.

After operating, whether with knife, saw, scissors, or trephine, care should be taken to remove all loose pieces of tissue, cartilage, or bone, with forceps ; the patient can assist by blowing the nose thoroughly. A layer of cotton wet with a solution of mercuric bichloride,1 to 2,000, may then be loosely placed over the wound, *not packed* into the nostril. Such a loose layer of cotton becomes a sufficiently tight plug to check bleeding when the effect of the cocaine has disappeared, and the tissues of the nostril have become somewhat swollen. Plugging the nostril tightly for the purpose of stopping hæmorrhage is usually unnecessary, and it causes painful irritation. We are in the habit of keeping patients at our office for ten or fifteen minutes after the operation. At the end of that time the loose cotton layer is removed, and if the bleeding has ceased, iodoform, iodol, or aristol may be dusted over the wound, and the wound again covered with a layer of iodoform gauze, or antiseptic cotton. Usually there is bleeding enough, to render the application of any powder impracticable, and the first layer of bichloride cotton is simply replaced by a second one, or by iodoform gauze, which is left in position for thirty-six or forty-eight hours. We have not been in the habit of washing out the nose with any antiseptic solution after operation, but have been satisfied to allow the patient to blow it thoroughly. We believe somewhat in the protection afforded by the blood coagulum. Roe advocates irrigation of the nostrils after operation with a hot solution of salt and bichloride, 1 to 4,000. It may be wise to check all bleeding by hot antiseptic irrigation, so that an antiseptic powder can be placed upon a fairly dry surface.

Dr. O. B. Douglas, of New York, recommends the use of the solution of aluminium acetotartrate, ʒ j. to ʒ iv., as a substitute for other antiseptics. Cotton may be saturated with this solution and placed upon the wound, and left in position for several days, it is claimed, without danger of wound infection.

After all covering has been removed from the wound at the end of forty-eight hours, the nostrils may with advantage be thoroughly cleansed with some one of the

antiseptic solutions already referred to, and the patient can accomplish all that is necessary by spraying the nostrils twice daily with a proper cleansing prescription. While there is little danger of infection through nasal wounds after the lapse of forty-eight hours, they require considerable attention for many days, to hasten healing and to prevent the outgrowth of granulation tissue, which will again block the nostrils.

Our belief may be stated briefly, in conclusion, that while it is impossible with our present knowledge and present methods to obtain a perfectly aseptic condition for nasal wounds, yet experience has demonstrated that patients suffer far less from constitutional disturbance after nasal operation, that bleeding is more surely controlled, and that nasal wounds heal much more quickly, when all reasonable antiseptic precautions are employed.

NEPHRORRHAPHY. During the past ten years two hundred and fifty cases of nephrorrhaphy have been reported. The operation may now be said to rest upon a secure basis. The number of cases reported has been sufficient to enable us to determine what danger attends the operation, and what benefits result from this procedure. The details of the operation have been perfected, and experience has proved that certain methods may be rejected as unsatisfactory. Several new methods for the firmer anchorage of the movable organ have also been introduced. Considerable light has been thrown on many of these procedures by experimentation on animals, which in recent years has been pursued, especially in France, with extreme care.

A movable kidney is no longer looked upon as a rare condition. It is difficult to determine exactly in what proportion of cases this abnormality occurs. A marked difference exists in statistics on this point. Thus Lindner claims that one woman in every six has a movable kidney, while most other observers estimate the proportion among females as one in two hundred or three hundred. In males it is a much more uncommon occurrence. I feel sure, however, that it is a condition which is often overlooked, as, unless especially sought for, it will rarely thrust itself upon the examiner's attention. I feel sure also that often symptoms are attributed to other causes which in reality are due to the mobility of the kidney. It is certain that in many cases no symptoms will be caused by this condition. It may be asserted, I think, that in the great majority of cases it is the cause of but little discomfort. In other cases it may cause considerable discomfort, but yet the suffering is not severe enough to demand resort to operative procedures for its relief. It is only in exceptional cases that the pain experienced by the patient is so severe that operation is demanded. There are a few cases where the symptoms produced are of considerable gravity, but which are not suitable for operation, because of the probability that the nephrorrhaphy will fail to relieve these symptoms. In such patients the mobility and displacement of the kidney is dependent on the general laxity of all the abdominal tissues, where an enormously pendulous abdomen has, by stretching the various ligaments, dragged down and displaced the various viscera. In such cases the displacement is so general that the symptoms complained of should not be attributed to the mobility of the kidney alone. I have seen two such patients on whom the operation of nephrorrhaphy had been performed by skilful operators without the slightest benefit.

It is only just to state that a few careful observers, both physicians and surgeons, are still rather sceptical as to the existence of movable or floating kidney, and a certain number of others who doubt the significance of this abnormality as a cause of severe symptoms, and who are still more doubtful as to the necessity or efficiency of any operation for relief of this condition. There is scarcely a man, however, who has devoted special attention to abdominal diseases, who questions the occasional occurrence of movable kidney, and while a few of such specialists do not look with favor upon nephrorrhaphy, yet this number is rapidly diminishing,

The existence of both movable and floating kidney has been proven by thousands of observations on the examining, operating, and autopsy tables. It is equally certain that such mobility is frequently the cause of painful, and in a few cases of grave, symptoms. It has been frequently proven that it is possible to secure fixation of the kidney by operation, and as a result of such fixation the patients have been entirely relieved of their sufferings. It certainly seems reasonable to conclude that with the methods now at our disposal we ought to be able to fasten the kidney so securely that it cannot break loose from its new attachments. If the sutures are passed directly through the substance of the kidney, and then through the muscles of the loin, it seems most rational to believe that such anchorage will, in the majority of cases, be permanent. The numerous cases where relief from all distressing symptoms has directly followed the operation, and where after a lapse of years there has been no return of the symptoms, would certainly seem to prove, almost beyond a doubt, that the permanent fixation of the movable organ has been accomplished. Still further proofs of the satisfactory results obtained are afforded by the patients with thin and lax abdominal and lumbar muscles, through which the kidney can be distinctly felt so firmly anchored in place that strong manipulation fails to move it from its bed. In one of my own patients this condition is very manifest, and on examination three years after operation the kidney can be felt firmly anchored in a situation which, it is true, is rather lower than is normal, but which is sufficiently correct to free her from all pain, which formerly had entirely incapacitated her from work. More than this, several cases have been reported where the firm anchorage of the kidney has been demonstrated both by autopsy and at secondary operations. Langenbuch reports a case where, several months after the original operation, he reopened the lumbar wound on account of a fall which the patient had received, and he found the kidney firmly anchored. Tillman has observed at autopsy, two months after operation, the kidney, which formerly had an extensive range of motion, firmly fastened by newly formed connective tissue permeated by numerous blood-vessels, and intermingled with masses of cicatricial tissue.

Nephrorrhaphy is a justifiable operation in any patient whose life is made miserable by the distress caused by the movable kidney. Indeed in such cases operation should be urged. In other cases where moderate discomfort only is experienced the nature and dangers of the procedure, and its chances for relief or complete cure, should be explained to the patient, and she should then be allowed to decide whether or not she prefers to undergo the operation. In all cases it is a good rule to insist on the trial of some form of bandage or support before nephrorrhaphy is undertaken. In comparatively few of the severe cases will a bandage be of benefit, but it is worthy of a trial. In no case, if the kidney is otherwise healthy, should nephrectomy be advised until nephrorrhaphy has failed.

Mortality.—The operation is a comparatively safe one. In more than two hundred reported cases only three

deaths can be attributed to the operation. One of these occurred in the practice of a surgeon who does not believe in antiseptic surgery, and another occurred in consequence of a dangerous method used in the fixation of the kidney. The mortality can be estimated as about one to two per cent.

In what proportion of cases may we expect to effect a radical cure? This is a difficult question to answer categorically. The majority of cases cannot be watched for a sufficient length of time to be of much aid in this calculation. Certainly eighteen months or two years should elapse before we can decide that a permanent cure has been effected. The proportion of permanent recoveries ranges from fifty to seventy-five per cent., and of the cases operated on during the last four or five years it certainly will reach this latter figure and perhaps exceed it. By permanent cure I mean fixation of the kidney and permanent relief from all bad symptoms. A certain proportion of cases are improved, while in others the kidney appears to be fixed and yet the symptoms persist. In this latter class of cases the diagnosis has probably been incorrect. Out of my own 11 cases of nephrorrhaphy 2 have been complete failures, 6 have resulted in complete cure, 1 has been improved, and 1 has disappeared from view.

Operation.—The object is to firmly anchor the kidney in as near its normal situation as is possible. A number of different methods have been and are employed, but all procedures are alike in one point, that they aim to fasten the kidney to the lumbar muscles by means of sutures. They differ in two points, the nature of the suture material and the tissues which the sutures penetrate. The patient should be placed in such a position as will make the space between the last rib and crest of the ilium as long as possible. This can best be accomplished by placing the patient partly on the side opposite to that on which the operation is to be done, and partly prone. Pads should be placed under the abdomen, and crowding up under the opposite ileo-costal space so as to make as prominent and large as possible this space on the side on which the operation is to be performed. The usual antiseptic precautions should be carefully carried out, thorough scrubbing with green soap, washing off with alcohol or ether, followed by the antiseptic or aseptic solution favored by the operator. The incision down to the adipose capsule of the kidney is made as in other operations. It may be either oblique, an inch below and parallel to the last rib, or vertical, along the outer edge of the erector spinæ muscle. The latter incision is the one I very much prefer, and is the one generally adopted in nephrorrhaphy. The oblique incision, while perhaps equally as serviceable in other operations on the kidney, is, for the purposes of this operation, inferior to the vertical. The skin incision is made from the last rib to the upper border of the crest of the ilium, along the outer border of the erector spinæ muscle. After division of the skin and cellular tissue and lower fibres of the latissimus dorsi muscle, the sheath of the erector spinæ is opened and this muscle is crowded inward by retractors toward the spinal column. The division of the middle layer of the lumbar fascia follows and the exposure of the quadratus lumborum muscle, which is easily recognized by the direction of the coarse fibres from above downward. This is also crowded inward and the anterior layer of the lumbar fascia divided and the perirenal fat (adipose capsule of the kidney) exposed. During the operation it should be remembered that the pleura extends down to the twelfth rib, and sometimes a little below it, and care should be exercised to avoid opening it. This accident happened to me in one case, where the pleural cavity was punctured at a point one-eighth inch below the last rib; no bad consequences followed. The kidney can by pressure from the abdomen be pushed into the wound, and it then remains to fasten it in place in its normal situation behind the twelfth rib.

The following different plans have been adopted: 1. The adipose capsule, opened or unopened, is united by sutures to the edges of the incision. This was Hahn's original operation, but it is now nearly abandoned. 2. After freely opening the adipose capsule the sutures are passed through the fibrous or true capsule of the kidney. This is a method which has been often successful, but is gradually being susperseded by one of the following methods, which seems to promise better results. 3. After free exposure of the kidney the sutures are passed directly through its parenchyma. They are passed through a considerable portion of the substance of the kidney, and at such a depth that they completely control its movements. Two or three such sutures are used, and they penetrate the kidney for a distance of about an inch and a half, and at a depth of one-fourth to one-half inch below its surface. 4. The fibrous capsule is divided vertically for a distance of two to three inches, and peeled off the kidney on each side till a raw surface of considerable extent is made, which is then brought into contact with the cut tissues in the loin. The sutures are then passed as in the last method, entering and emerging through the capsule just outside the raw margin. It has been found from experimentation on animals that, when the kidney, deprived of its capsule, is brought into contact with the cut muscles of the loin, the union resulting is far firmer than when the unbroken capsule is brought into apposition with the same structures. The results of operation seem to be in accord with these experiments. The division of the capsule is supposed also to serve another useful purpose in the relief of tension from the kidney itself. The last-mentioned method appears to me to be the securest.

I have operated according to the latter in four cases, and in none of them has there been any sign of relapse. The method does not seem to be attended with any special dangers. As far as we know at present the passage of sutures through the parenchyma of the kidney does not appear to cause any disturbance, either immediate or remote. It is even the exception to find red blood-corpuscles in the urine after these operations. Care should be taken, however, that the sutures are not tied too tightly, as otherwise they might cut the kidney tissue. I prefer to pass them threaded on a common round sewing-needle through the kidney itself. They can then be drawn through the muscles on each side of the incision by means of a handled needle. My own plan before tying these sutures is to unite the cut muscles carefully by means of buried sutures, thus shutting off the kidney from view, and then to tie the kidney sutures over the united muscles. In this way no tension is placed upon the kidney sutures. The skin is then united, and if deemed best a drainage-tube placed at the lower angle of the wound. In my later cases no drainage has been employed; but if there be any doubt about the absolute sterility of the wound, sponges, instruments, or dressing, then by all means a drain should be inserted. Formerly it was the custom not to close the external wound by sutures but to leave it entirely open, packed with gauze, so that it might fill up with granulation tissue. It was considered that the adhesions so formed by means of granulation tissue were firmer than those obtained by a primary union.

Various materials have been employed for sutures—silk, catgut, kangaroo tendon, silkworm-gut, and silver wire. The important point is that the material be thoroughly aseptic. Probably chromicized catgut and silk are the best materials. The former will hold for several weeks and will then disappear. The latter will become encapsulated, as a rule, and cause no disturbance, but occasionally the system will not tolerate its presence, and it will be eventually discharged through a sinus. Silkworm-gut and wire, while easily made aseptic, and while very unirritating and durable, may be apt to cut the kidney tissue. A number of operators, principally of the Italian school, consider it wise to fasten the upper end of the kidney at a higher point than can be reached by the ordinary incision. To accomplish this they have resected the twelfth rib in whole or in part, and sometimes the eleventh as well. To the periosteum of these ribs the sutures are fastened. In a few cases they have been attached to the periosteum without removal of the rib. This appears to

be an unnecessary procedure. It must certainly add to the dangers of the operation, and in one case it was to some extent responsible for a fatal result. Schachner has performed a number of experiments upon animals in the endeavor to replace the sutures "by natural stays in the shape of a pocket formed between the transversalis and internal oblique muscles." The method was successful in animals, but it remains to be proved whether or not it will be of advantage in the human subject.

The subsequent treatment of the case is of importance. Considerable neuralgic pain is felt for the first week, or longer, shooting down toward the groin. This can be quieted in the usual way by opiates. It is of great advantage to keep the patient flat on the back for two or three weeks at least after the operation, and rest in bed should be maintained for another two weeks. This will necessitate confinement to bed for about five weeks, and another two weeks should elapse before the patient can resume business of any kind. No violent exercise should be attempted for at least four months. In a few cases lumbar hernia (of the kidney through the cicatrix) has followed nephrorrhaphy, but it is an accident of very rare occurrence. *Andrew J. McCosh.*

NERVES, REGENERATION OF. A reunion by first intention of the severed ends of a nerve can no longer be doubted, although such instances are rare. This desirable result is owing largely to the adoption of the most rigid antiseptic precautions, and when obtained the return of sensation begins within about twenty-four hours, soon to be followed by a return of motility.

The most valuable contribution yet offered on this subject has recently been published by Howell and Huber (*Journal of Physiology*, xiii., No. 5, 1892). Their investigations were partly physiological and partly histological.

With a single exception dogs were used. The nerves experimented upon were the ulnar of the two sides, and in case of cross-sutures, the median and ulnar. Antiseptic precautions were observed. Carbolized catgut, or catgut in juniper, was used for sutures. The cut ends of the nerves were in almost every case brought together by one suture on each side which passed through the epineurium, wounding the nerve-fibres as little as possible. In most cases the nerve was lifted with a thread and cut with sharp scissors. After a certain time the nerve was laid bare and irritability tested in various ways, and subsequently histological examinations were made.

The chief results of this research are as follows:

In none of the experiments was there union of the cut ends by first intention. In all cases the peripheral end degenerated completely throughout its entire length. During the first four days there gradually occurred a complete loss of irritability and conductivity in both sensory and motor fibres, which lasted until regenerative changes, as shown by histological investigation, set in.

Irritability in all cases appeared first, after union was made, in the neighborhood of the wound, and from that part spread centrifugally, apparently with great slowness. The gradual increase in irritability at any one level seemed to go hand in hand with the increase in the number of newly-formed fibres, and not with a progressive regeneration in the single fibres. The return of irritability to the sensory fibres was in advance of that to the motor fibres. With the beginning of the return of irritability mechanical stimulus was more efficient than electrical stimulus. This, the authors believe, is due to the fact that the nerve-fibres in the process of regeneration are in the embryonic stage, possessing but a low degree of irritability, and that the more violent mechanical stimulation is necessary to arouse them.

Conductivity appeared before irritability. In other words, the nerve conducted impulses before it became excitable to direct stimulus.

The return of function, which began to appear at the end of three weeks, was not perfect at the end of seven weeks, although nearly so at the end of eleven weeks.

Although functional activity returns first to the fibres near the wound and spreads centrifugally, it does not follow from this that the fibres which first branch off from the trunk and have the shortest route to travel are the first to regenerate.

The possibility of the functional union of two spinal nerves is proven, but indicates that the time required for the regeneration of the nerve-fibres is longer than in the union of the two ends of the same nerve.

After complete severance from the nerve-centres of the peripheral end of the nerve, degeneration occurs throughout its entire extent.

The degenerative changes and the subsequent regeneration take place as follows: (*a*) Segmentation of the myeline and axis at the intersegmental lines; (*b*) proliferation and migration of the internodal nuclei; (*c*) secondary fragmentation and absorption of the myeline (and contained *débris* of the axis), most active in the neighborhood of the nuclei; (*d*) increase of protoplasm round the nuclei, forming finally a continuous sheath band of protoplasm lying in the old sheath; (*e*) formation of a new sheath on the periphery of this band, thus making an "embryonic fibre;" (*f*) union of the embryonic fibres of the peripheral end with those similarly formed in the central end, the union taking place in the intervening cicatricial tissue; (*g*) formation of myeline in the peripheral end as isolated drops, usually seen first near the nuclei. These afterward unite to form a continuous tube. The formation of the myeline proceeds centrifugally, starting from the wound; (*h*) the outgrowth of new axes from the old axes of the intact fibres of the central end, the outgrowth following quickly upon the development of the myeline: (*i*) in the central end, and especially when connection with the periphery is not made, several new fibres may form within the sheath of an old fibre to take the place of the portion degenerated. Each of these may develop myeline and receive a branch from the axis cylinder above. *Edward T. Reichert.*

NERVOUS SYSTEM, COMPARATIVE ANATOMY OF THE. RECENT PROGRESS.—The field is so large and the accumulated literature of the last few years so enormous, that it has seemed best to select typical or representative episodes, and to present data from various sources without attempting to edit them compactly or to assimilate them fully into a complete and orderly whole. This procedure is in harmony with the existing state of the science, which hurries from one discovery to another without intermission, and it will only be profitable to make a complete summary after the possibilities of the modern technique have been measurably exhausted. While it is not claimed that the selection has been as discriminating as could be desired, and many valuable additions to our knowledge are unwillingly passed over in silence, we trust that sufficient material has been collated to indicate the tendencies of modern research. The classes of vertebrates are taken up in succession and afterward a few special topics are discussed.

Amphioxus.—Hatschek [1] has added valuable points to our knowledge of this simplest vertebrate. The results seem to warrant the hope that the perplexing problems of cerebrogenesis may yet be solved by comparative methods.

The spinal cord of Amphioxus contains a circular canal which extends dorsad in a delicate cleft nearly to the dorsal surface of the cord. The canalis centralis is surrounded by gray matter, which extends to the dorsal surface, but on all other aspects is clothed with white fibres.

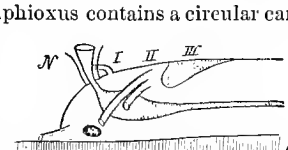

FIG. 431.—Longitudinal Section through the Brain of Amphioxus when young. *I, II, III.* vesicles; *N*, Sensory pit, which is homologous with the pituitary; *ch*, chorda.

In the young the brain consists of a cephalic enlargement of the medullary tube, which subsequently is obscured. In a later stage, three vesicles are indicated corresponding to the primary embryonic vesicles.

The first of these sections (primary prosencephalic vesicle) contains a distinct ventricle. From the cephalic

extremity of this cavity, the infundibulum is formed. It is an expansion of the brain-wall which comes into direct communication with the ciliated pit of the dorsal surface of the head. The communication is subsequently closed. The cavity of the second vesicle is a mere tube, which has been compared (with doubtful propriety) with the aqueduct. The third vesicle has a dorsally located fossa rhomboidea with membranous dorsal roof.

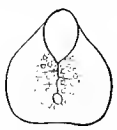

Fig. 432.—Cross Section in the Region of the Third Vesicle.

The brain in the young is in the region of the first and second segments. The ciliated frontal pit is connected by an olfactory nerve with the front of the brain. The pit is homologous with the hypophysis and nasal sac of craniates. A comparison with Ammocoetes and higher vertebrates shows that, in the latter, the infundibulum (and with it the whole brain axis) has been flexed ventrad.

The spinal nerves have the usual divisions. The dorsal root does not communicate with the ventral, but passes toward the periphery, where it divides into a dorsal and ventral ramus. The ganglion is represented by numerous cells scattered in the nerve near its point of division, and thus near their origin. This is very suggestive as to the origin of the spinal ganglion.

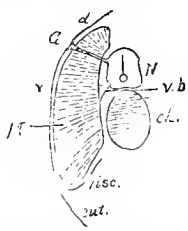

Fig. 433.—Cross Section of Body (diagrammatic). *N*, nerve tube; *ch*, chorda; *M*, muscular segment; *G*, dorsal branch, with ganglion cells passing through the muscles and dividing into a dorsal ramus (*d*) and ventral ramus (*v*), the latter again dividing into a cutaneous and a visceral branch; *v.b*, motor root.

The dorsal ramus gives off a cutaneous dorsalis and lateralis dorsalis nerve, and the ramus ventralis similarly divides into a cutaneous ventralis and lateralis ventralis. In addition to these, the ventral ramus affords a special visceral branch. There is a tendency to the formation of plexi, aud it is thought that many of the fibres may be sensory. It has been compared with the vagus, but a similar branch is found in the dorsal regions. The ventral root is the special nerve to the trunk muscles, and is purely motor. The sensory (dorsal) branch is intersegmental, the ventral segmental.

The first pair of nerves lies along the dorsal side of the cord (and the rostral muscles of the larva), and supplies the epithelium of the cephalic end of the rostrum. Some of the branches are supplied with Quatrefages' ganglion cells.

The second nerve consists of an anterior portion, distinct nearly to the root, which gives off a strong lateralis dorsalis and ventralis; these supply the remainder of the rostrum. The second portion divides into two cutanei dorsales, a cutaneous ventralis and a cutaneous visceralis, which latter innervates the buccal muscles.

The third to fifth nerves have the normal form (as above). All the viscerales unite in a plexus to which the fourth and fifth supply especially strong contingents. The separate descending branches pass to the muscles of the mouth and velum, while a strong branch, which fuses with a branch from the sixth and seventh, passes to the plexus of the branchial apparatus.

The fifth nerve gives off an especially large visceral branch which supplies a strong branch to the sensory organ of the right side (derived from the ectoderm of left side).

It is regarded as probable that the first nerve is homologous with the ophthalmicus profundus, and the ventral nerve of the rostrum with the maxillaris.

Ammocœtes.—The additions to our knowledge in the Cyclostomata have related chiefly to the homologies of the nerves. Hatschek[1] shows that there is a great similarity, in general, with the distribution prevailing in fishes and the embryological data discovered by Kupffer.[3] The cranial nerves also show the same fundamental parts as already reported in Amphioxus. The dorsal root produces (*a*) a ramus dorsalis, which divides into a cutaneous dorsalis and a lateralis dorsalis, and (*b*) a ramus ventralis, which represents a cutaneous and prætrematicus, and also gives off strong rami viscerales and the cutaneous ventralis, which together form the "post-trematicus."

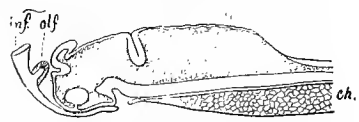

Fig. 434.—Longitudinal Perpendicular Section of the Brain of Ammocœtes, for comparison with the similar view of the brain of Amphioxus (Fig. 431). *ch*, chorda; *olf*, olfactory sac; *inf*, infundibulum.

The visceral branches carry motor fibres to supply the muscles of the mouth and gills, as well as sensory fibres to the mucous membrane.

There is a longitudinal set of connecting fibres uniting all nervi laterales dorsales, the continuation of which forms the recurrens lateralis of the vagus, extending the whole length of the animal. This longitudinal system is related with the sensory organs of the lateral line. This system embraces (dorsad and ventrad) the eye. The important morphological deduction from the above fact is that the nervus lateralis vagi is phylogenetically formed of the nervi laterales of all the spinal nerves, the direct connection with which has been subsequently lost.

Another longitudinal set of connecting fibres brings all the ganglia of the rami ventrales into communication (this arrangement is complete only in the young). The epibranchial sensory organs (organs of the ventral lateral line) are supplied by nervi laterales ventrales which branch from each of the rami prætrematici. It appears from a comparison of these types that there is essential similarity between the cranial and spinal nerves, but it is the latter and not the former which have been altered.

The trigeminus is now generally recognized as combining two nerves. Hatschek distributes the cranial nerves and head organs as indicated in the table on page 671.

In a subsequent paper[5] Hatschek announces the discovery that the dorsal roots, in all higher vertebrates, connect with the ventral root next caudad, and their branches follow the myoseptum. Thus the ventral roots are segmental, and the dorsal intersegmental. The arches are intersegmental, and the clefts are segmental. This simplifies the above scheme without invalidating the facts.

Edinger[6] describes the olfactory nerves of Ammocœtes, in which he recognizes a commissure and a chiasm which are in direct connection with the interlobular (anterior) commissure. Unfortunately no one has yet studied the olfactory in the light of our present morphological knowledge, and the existence of a radix lateralis and hippocampal rudiment is still only conjectural.

Selachii.[6]—Edinger concludes, from a study of the embryology as well as from a comparison of the adult brain, that the forebrain of sharks and rays differs from that of all other (higher) vertebrates in that no true hemispheres are formed, but the primary prosencephalic vesicle persists, and the thickened walls contain the elements which in other groups constitute the hemispheres. The sharks are somewhat in advance of the rays and have slight indications of the subdivision.

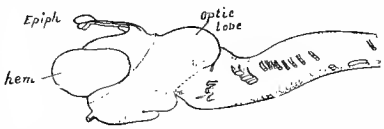

Fig. 435.—Lateral View of the Brain of Adult Petromyzon. *Epiph*, epiphysis; *hem*, hemisphere; *opt. l*, optic lobes.

The same author gives a detailed description of the diencephalon. The latter is divided into a cephalic and a caudal portion into which the pedunculi cerebri enter from the prosencephalon. The habenulæ of the two sides differ greatly in size and are connected by a commissura habenaria. The caudal or infundibular part of the diencephalon has two lateral lobes and a posterior (caudal) lobe, and bears a large hypophysis, saccus vasculosus, and

recessi laterales infundibuli (mammillaria.) In adults the hypophysis consists of coiled and branching pouches. The histological structure is much as in bony fishes.

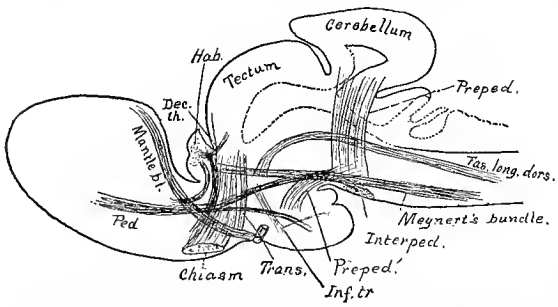

FIG. 436.—Longitudinal Section of Selachian Brain, according to Edinger. The brain is supposed to be transparent, and the various fibre systems are projected upon one plane.

Nerve-fibres are said to arise in the infundibulum, but the writer has found only gelatinous fibres in the corresponding organ of fishes.

The peduncuti divide into a dorsal and ventral tract, the latter terminates in the infundibular portion, the

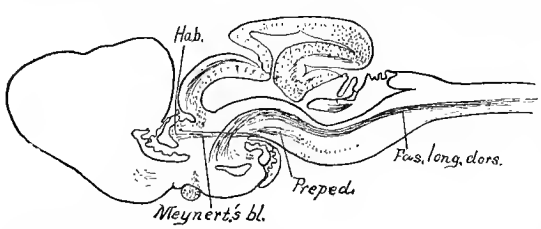

FIG. 437.—Diagrammatic Representation of a Section of the Brain of Scyllum.

former passes beyond the diencephalon. A tract which requires further study is the so-called "mantle tract," which is said to originate from the dorsal part of the prosencephalon and decussate caudad of the chiasm and ventrad of the commissura transversa. After decussation the fibres pass to the deeper layers of the tectum opticum. The commissura transversa is identified with von Gudden's commissure. A tract is described from the habenæ to the roof of the mesencephalon, also a tract to the prosencephalon comparable with the tænia thalami. The ventricular cinerea gives rise to decussating fibres. Most of the fibres of the diencephalon spring from the pars infundibularis, among them the fasciculus longitudinalis dorsalis. This bundle seems to receive a contingent from the region of the oculo-motor and passes into the ventral columns of the cord. The prepeduncuti of the cerebellum arise from the region where the ventral peduncles disappear.

THE BRAIN OF DIPNOIDS.—The lung-fishes have long been recognized as of great morphological interest by reason of their primitive and intermediate position. The combination of embryonic characters in the skeleton and limbs with amphibian peculiarities of the circulatory and respiratory systems makes them very instructive in indicating the possible primitive condition of the vertebrate phylum. The neurology of the African lung-fish, *Protopterus*, has recently been carefully investigated by Dr. R. Burckhardt.* The relations of the brain of different groups of vertebrates may be expressed somewhat as in the following diagram, which, however, differs in several points from that given by Burckhardt:

Primitive vertebrate. { Lamprey. —— Sharks. Rays. —— Dipnoids. } —— { Ganoids—Bony Fishes. Ichthyophis—Amphibia. ———— Mammals. Reptiles——Birds. }

The resemblances to lampreys (Petromyzon) is very great, in spite of certain reductions in the latter, due to retrograde metamorphosis.

Ganoid Fishes.[8]—Professor Kupffer has studied the development and discusses the morphological results. He states that at a period of forty-five hours after fertilization the brain is not yet separated fully from the epidermis. It is of great morphological importance to determine at what point the attachment is effected.

Only two vesicles are clearly distinguishable, the cephalic being the smaller. Growth is at first more rapid in the ventral part of the tube and this gives rise to a

"*plica encephali ventralis*" (*pl. vent.*). This is the floor of the mesencephalon and is the first indication of what in mammals is called the saddle-cleft. The roof, like the floor of the brain, consists of simple epithelium. The first indication of the pineal appears near the middle of the roof (*ep*², Fig. 443), nearly midway between mesencephalon and prosencephalon. Just caudad of the plica is the pons flexure. The slight curvature of the floor in front of the plica is constant in all vertebrates and is called by Kupffer "tuberculum posterior" in spite of the previous use of nearly the same term for the obscure corpora quadrigemina posteriora of Sauropsida, etc. The cephalo-dorsal part of the brain tube is open, and communicates by a tubular conduit with a space beneath the outer layer of the epidermis, while the brain-walls are continuous with the inner epidermal layer (at *r*, Fig. 443). Just below (ventrad of) this communication is the recessus opticus, on the caudal aspect of which the optic chiasm will develop, and on the cephalic aspect the anterior commissure. The hypophysis is at this stage of unexpected size and shape (*hy*), and it impinges on the front of the brain-tube. The organ is developed from the layer of cells where the entoderm and inner ectoderm layer meet in front of the head. It is in immediate connection with a thickened part of the inner ectoderm layer which is to

form the sucking disk (*hf*, Fig. 443), immediately above the mouth.

When the age of fifty-seven hours is reached (Fig. 444), the brain has elongated, the connection of brain and epidermis is now a solid cord of cells. The epiphysis has become more distinct.

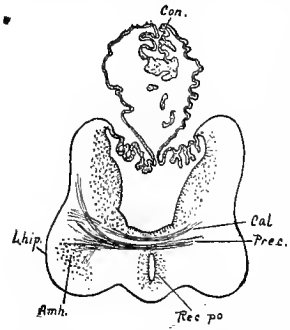

FIG. 441.—Section through the Precommissure of Brain of Protopterus. *Con.*, conarium; *L. hip.*, hippocampal lobe; *Cal.*, callosum; *Amh.*, cornu ammonis; *Rec. po.*, recessus preopticus; *Prec.*, precommissure.

From this time on the hypophysis begins to separate from the skin, with which it is for a long time connected by a stalk. The brain communication with the ectoderm is severed, and a slight protuberance at this point remains, which the author calls the tuber olfactorius impar.

The region of the future infundibulum (Fig. 446) becomes greatly expanded and several sinuses are developed. The inferior commissure system appears earlier than the chiasm fibres.

The tuber olfactorius impar, which Kupffer considers the morphological front of the head, and which was originally in juxtaposition with the hypophysis, becomes more and more widely separated from it and ceases to grow, and even becomes reduced. At the end of larval life (Fig. 446) the paraphysis *ep'* is derived from the prosencephalon in front of the dorsal sac.

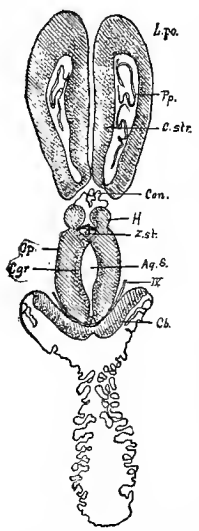

FIG. 442.—Longitudinal Horizontal Section through the Cerebral Hemispheres, etc., of Protopterus. *L. po.*, lobus post-olfactorius; *Pp.*, preplexus; *C. str.*, striatum; *H.*, habena; *Z. st.*, stipe of pineal gland; *Aq. S.*, aqueduct; *Cgr.*, axial gray matter; *Ch.*, cerebellum.

The velum transversum (*vt.*), which immediately precedes, begins to assume a plexiform appearance. The commissures are well developed. The star in Fig. 446 indicates what the author and Burckhardt regard as the caudal limit of the base of the mesencephalon. Two commissures of the infundibulum are called com. debelis (*de*) and com. terminalis (*t*), though it is hard to see what excuse can exist for these new terms. The author identifies the com. debelis with Edinger's decussatio infundibuli. The dorsal sinus of the infundibulum becomes the hypoaria, and the ventral becomes the saccus vasculosus, though also producing two lateral vesicles which are probably the homologues of the similar sacs of Teleosts which Herrick has homologized with the mammillaria.

Kupffer concludes that his researches settle the question as to the morphological front of the brain. Baer, His, and the writer have contended that the region of the infundibulum is the front, while Reichert and Kölliker locate it in the terma in front of the chiasm. Mihalkovics locates the theoretical front in the middle of the terma and denies the existence of a "hook-curvature" of the axis. Von Wijhe shows that the point of attachment of the brain with the skin is independent of the hypophysis. Kupffer completes this argument by discovering a median olfactory fundament.

The Ganoids have a much greater development of the roof of the diencephalon than is characteristic of the Teleosts and Selachii. The greatly distended base of the diencephalon Kupffer designates as hypencephalon. The most caudal part of this segment gives rise to the hypoaria, which the present writer, on embryological grounds, has been tempted to relegate to the base of the mesencephalon.

Regarding the whole cavity cephalad of the mesencephalon as a single vesicle, Kupffer arranges the secondary modifications of its walls as follows: 1. From the cephalic wall, the optic vesicles and stalks. 2. From the dorsal wall, the epencephalon (= cerebrum), the paraphysis or anterior epiphysis, the parencephalon (diencephalon), the epiphysis proper. 3. From the floor, the hypencephalon with the saccus dorsalis, hypoaria and saccus vasculosus.

The author makes much of the fact that there is in Amphibia a large postpineal part of the roof which is absent in the Ganoids.

The adult brain has been recently examined by Goronowitsch[10] in Acipenser, and by Herrick[11] in Scaphirhynchus and Lepidosteus. The following extracts from the paper of Goronowitsch will be useful:

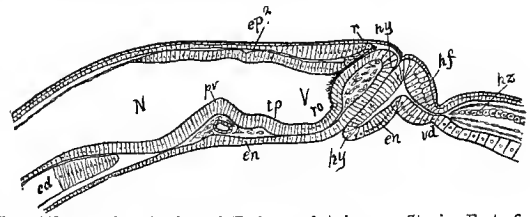

FIG. 443.—Median Section of Embryo of Acipenser Sturio, Forty-five Hours after Fertilization.

"*Cerebrum.*—The roof of the prosencephalon is membranous, and consists of a variously folded epithelial lamina. The roof of the olfactory lobes, however, consists of thick medullary walls. Between the roof of the prosencephalon and the epiphysis there is a broad membranous sac, the cavity of which is distally in wide connection with the cavity of the prosencephalon. The blind end of the sac is directed proximally (cephalad!). The sac, therefore, must be considered as a broad diverticle of the roof of the prosencephalon, springing from a point cephalad to the origin of the epiphysis. This may be called, for the sake of brevity, simply the dorsal sac.

"At the anterior margin of the left ganglion habenula (the left is much the smaller) a lateral induplication of the membranous roof of the prosencephalon enters the ventricle. This fold is somewhat complicated. The epithelial layer of which it consists forms numerous folds and sacs, into which projections of the membranes and blood-vessels enter. The structure is, in other words, that of a plexus choroideus.

"Careful study of continuous series of sections indicates that there is nowhere a discontinuity in the epithe-

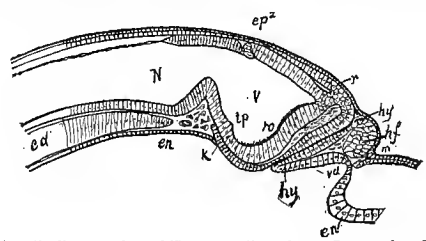

FIG. 444.—Similar Section of Embryo, Sixty-four Hours after Fertilization.

lial layer. The cavity of the prosencephalon is therefore completely closed. The dorsal lamina of the fold forms the ventral wall of the dorsal sac, and the ventral lamina forms the membranous wall of the prosencephalon. It thus appears that the opening of the dorsal sac is asymmetrical. Cephalad from this point the two chambers are separate. The ventral portion of the neural tube at this region consists of thick paired masses, the basal ganglia. The membranous roof bears a system of

folds which becomes more complicated. The middle portion projects into the ventricle and forms a sort of falx cerebri. The dorsal wall also circumscribes the dorsal sac laterad and encloses it in a plexiform structure derived from the roof the prosencephalon.

"Somewhat cephalad of the base of the olfactory lobes a groove appears upon the dorso-median aspect of the basal ganglia, which passes mesad and can be traced directly into the cavity of the olfactory lobe. The median falx of the roof dips deeply into the ventricle of the prosencephalon. The falx extends to the epithelial lamina which connects the two olfactory lobes. Cephalad of this point the membranous roof of the prosencephalon is continued to form paired sacs dorsad of the olfactory lobes.

"In this structure of the prosencephalon of A. ruthenus I detect the paired nature of the prosencephalon, which consists in the strongly developed falx as well as the membranous sacs of its cephalad portion.

"At the cephalic level of the chiasm two prominences appear upon the dorsal portion of the encephalon wall which have the structure of the basal ganglia. This structure extends soon to embrace the entire lateral walls of the prosencephalon. These ganglia consist of a very compact, finely granular stroma, with peculiarly arranged ganglion cells, and of a system of exceedingly fine, non-medullated fibres. Beneath the epithelium, in the dorsal region of the ganglia, is a layer of small cells whose fibres extend ventrad and radially. Such cells are not found in the ventral portions, but instead irregularly scattered small cells. In the midst of the ganglion are large cells with large round nuclei and pale body. The processes are also radially disposed to the ventricular surface, producing in cross-sections a very characteristic habitus. The transition in structure in passing into the olfactory lobes is gradual.

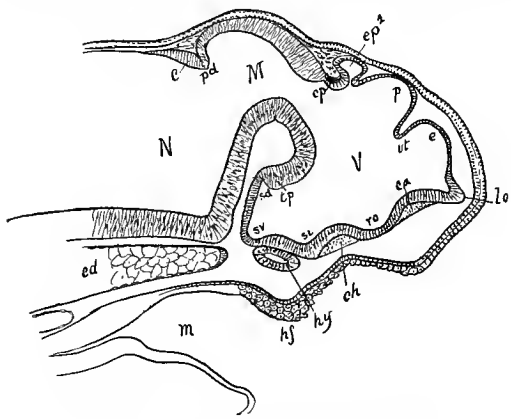

FIG. 445.—Similar Section of Larva, Three Days Old.

"The cephalic ventrally arched end of the embryonic nerve-tube, which, according to Götte, forms the primitive prosencephalon, is to be regarded as the most primitive phyletic condition of the prosencephalon which ontogony suggests. The primitive prosencephalon is homodynomous with a segment of the spinal cord. By the growth of the dorsal surface of the primitive prosencephalon arose the discrete central organ of smell, while the lobus infundibuli is the result of a protrusion from its base. The formation of the olfactory centre led to the development of the prechordal portion of the skull. The architecture of the cranium of the most primitive of the Gnathostomata, the Notidaidæ, corresponds to that of the brain. The gradual development of the organ of smell gave rise to the rhinencephalon of recent Selachii. This still indifferent organ exhibits no special homologies with the diencephalon and prosencephalon of higher vertebrates. It is closely connected with the lobus infundibuli, which is reduced in higher vertebrates.

"On one hand, the reduced form of rhinencephalon of Ganoids and Teleosts is derived from the rhinencephalon of Selachii, which, on the other hand, give rise to the structure of the prosencephalon in Dipnoii, Amphibia, and Reptilia. It is among these forms that the first indications of the origin of the prosencephalon of higher vertebrates may be sought. The first step toward the higher organization consists in the reduction of the lobus infundibuli and a transformation of the tracts connecting with the caudal parts of the nervous system. The development of the thalami and the reduction of the lobus infundibuli alters the development process of the neural tube in higher vertebrates from the earliest stages on. There appears a diencephalic and a secoudary fore-brain, the former having an entirely different significance from the posterior part of the prosencephalon of fishes, for it is the result of accelerated development of a certain dorsal portion of the neural tube which remains undeveloped in fishes. With the gradual development of the thalami and alteration of the rhinencephalon of Selachii, there gradually arise the tegmentum cruris and the pes pedunculi of higher vertebrates.

"*The Thalamus.*—The lateral walls of the lobus infundibuli form two round, lateral projections, the lobi inferiores, containing a considerable cavity. The posterior part of the lobe extends into a membranous sac, the so-called saccus vasculosus. Ventrad, the lobe connects with the bilobed hypophysis.

"The walls of the lobus infundibuli consist of finely granular stroma, staining pink with carmine, resembling that of the peripheral portion of the cerebellum. In the peripheral portion this stroma is compact, and it requires high powers to make out a fine fibrous structure parallel to the surface. Two fibre systems are more obvious entad. The fibres of the first run parallel to the surface, those of

the second radial to the surface. The latter spring from a layer of tissue clothing the inner surface. This layer is composed of a few series of round cells, much resembling those of the granular layer of the cerebellum. They are, however, somewhat larger than the latter, and the dark protoplasm mass surrounding the round nucleus of these cells is more highly developed. It is possible to trace the processes of these cells into the fibres of the radial system. In the fibrous zone round cells are scattered, as well as rod-like cells of the neuroglia.

"In the ventral portion of the cleft-like canal connecting the lobus infundibuli with the mesencephalic ventricle a ganglionic body composed of large cells occupies either side. Out of these ganglia springs a tract of non-medullated fibres which, passing caudad, subdivides, part of the fibres passing to the caudal part of the lobus infundibuli, and part to the dorsal portion of the sacculus vasculosus. Associated with this system is a rather large bundle of non-medullated fibres derived from a small cluster of nerve-cells lying dorsad to the above-mentioned ganglion and ventrad to Meynert's bundle, immediately beneath the epithelium. The ventral portion of the caudal wall of the lobus passes into the thin epithelial wall of the saccus vasculosus, a part of the fibrous layer entering it. The saccus itself is a broad, very vascular, folded sac, clothed within by a peculiarly modified epithelium.

"The discoidal *hypophysis* consists of two completely distinct parts. The caudal portion is composed of three or four lobes, into each of which passes a thick bundle of non-medullated fibres, which passes to the ventral portion and subdivide in the several sacculi. The saeculi of the cephalic portion are covered, like the former, with multilamellate epithelium with fusiform cells, but no nerve-fibres are present. The interstitial substance is connective tissue only. A thin layer of epithelium connects the two portions.

"*The Ganglion Habenulæ.*—Cephalad of the ganglion interpedunculare and ventrad of the transverse fibres of the commissura ansulatæ, there are two longitudinal bundles, which could be followed caudad only to the interpeduncular ganglia. These are Meynert's bundles, the right being much stronger than the left. The bundles pass cephalad and mesad of the fibres of the oculo-motor, and gradually pass dorsad, and at the point of communication of the ventricle of the lobus infundibuli with the mesencephalic ventricle they lie adjacent to the epithelium. These bundles terminate cephalad of the anterior commissure in the ganglion habenulæ."

Herrick, in speaking of Lepidosteus and Scaphirhynchus adds: "The lateral ventricles are not absent, nor are they merged in the olfactory ventricles, as stated by others. A section taken at a point in front of the foramen of Monro in the sturgeon brain shows that a cavity clothed by tela choridea (or pallium) extends cephalad along the dorso-mesal surface of each olfactory lobe. This cavity is of great morphological importance; part of its walls are modified to form a plexus, and it comes into direct communication with the aula. The surface of the lobe bordering is, like other ventricular surfaces, covered with epithelium. The cellular structure is also unlike that of the remainder of the lobe. It seems unquestionable that this space is homologous with the cavity of the lateral ventricle, which is not roofed over with nervous matter, but has merely the tela or pallium. These two ventricles become confluent cephalad to the

Fig. 448.—Transection at the callosum, *c.c.* *v.l.*, lateral ventricle; *m.*, membranous roof of the ventricle corresponding to the mantle; *a.l.*, axial lobe of the cerebrum: *f.M.*, foramen of Monro; *gl.*, remnant of the glomerular layer of the olfactory; n^1, olfactory nidulus beneath the aqueduct of the olfactory. Fig. 449.—Transection back of the chiasm. A mesad protuberance of the axial lobe corresponding to a part of the striatum is separated by projections of the ventricle. The aula is partly confluent with the ventricles. *v.l.*, spur of the posterior cornu passing cephalad. In the connecting portion uniting the thalamus and hemispheres some evidence of the tænia thalami was detected. Fig. 450.—Transection at the level of the habenæ. The lateral ventricles have completely circumscribed the axial lobe. *c.g.e.*, corpus geniculatum externum; *n*, lateral nidulus of the thalamus; *Hy.*, hypophysis; *n.M.*, nidulus Meynerti; *f.M.*, foramen of Monro. Fig. 451.—Transection through the posterior commissure. A portion of the epiphysis is seen above, *ep.* *S.c.*, commissura Sylvii; *Pc.*, post-commissura; *M.b.*, Meynert's bundle; *Ha.*, Hypoarium. Fig. 452.—Transection at the middle of the optic lobes. *III*, third nerve in a groove between the hypoaria and lateral lobe of the thalamus. The tori project medianly into the ventricle. Fig. 453.—Transection through the posterior part of the optic lobes. *IV*, fourth nerve; *vol.*, volvulus, or portion of the cerebellum thrust into the optic ventricle. Fig. 454.—Transection through the medulla and cerebellum at the opening of the recessus lateralis.

openings of the olfactory lobes, but a partial division, by a depending loop corresponding to the dorso-mesal walls of the mantle, may be traced back of that point. From the ventral extension of these median walls two arms, forming with them an irregular inverted Y, pass laterad nearly to the ectal thickened walls of the hemisphere, shutting off a median aula from the lateral ventricles, with which the former is connected by a large portæ. It is from the ventricles thus bounded, and not from the median chamber, that the olfactory aqueduct springs.

"The development of nervous matter in the cerebrum is greater relatively in the gars, therefore the membranous portion of the mantle is greater in Scaphirhynchus. In Lepidosteus the ventricle gives off two spurs in the median portion delimiting a body somewhat resembling the corpus lenticulare of the striatum. The posterior cornu sweeps back of the crura and then circumscribes the ventral and ectal portions of the cerebrum, finally meeting the dorsal extension of the ventricle, enclosing a large occipito-basal lobe much as in reptilia. The extent of the ventricle may be most easily recognized by the epithelial covering of the axial lobe where it is present.

"The cerebrum is more highly developed in Lepidosteus. Cephalad, it projects beyond the olfactory, and appears in transection as two independent bodies dorsad to the olfactory lobes. Fig. 447 illustrates a section through the olfactory and extreme cephalic part of the lateral ventricle, which is bounded only by the pallium. The relations are essentially the same in all Ganoids. Fig. 448, which passes through the callosum, shows the relation between the olfactory aqueducts and lateral ventricle. The real homologues of the foramina of Monro are considerable slits. In the sturgeon the relations are similar, but the partial eversion of the hemispheres laterally brings the openings of the aqueduct of the olfactory lobes farther laterad.

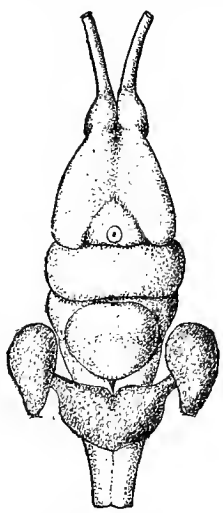

Fig. 455.

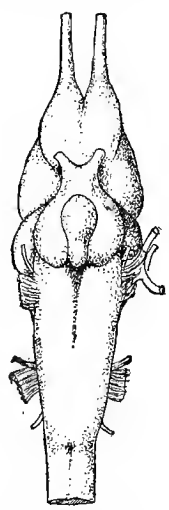

Fig. 456.

Figs. 455 and 456.—Dorsal and Ventral Views of the Entire Brain of the Gar. The bi-lobed mass lying behind the cerebellum is not of a nervous character.

"Respecting the *dorsal sac*, Lepidosteus affords much clearer information than the sturgeon, and renders necessary a considerable change in the interpretation of this structure offered by Goronowitsch. Morphologically it is a dorsal pouch of the diatela, such as may be detected in all reptiles in which the epiphysis is strongly developed. The asymmetry upon which Goronowitch lays so much stress is slight, and more apparent than real. The fact that it extends so far cephalad between the hemispheres is an incident to the cephalad projection of the epiphysis. It may be useful to first study the structure of the latter.

"The *epiphysis* springs from the most caudal portion of the recessus pinealis, which is clothed, as usual, with very large and dense epithelium, very different from that of the adjacent parts of the third ventricle. There seems to be a perforation passing obliquely dorso-caudad, forming the communication between the cavity of the epiphysis and the recessus. The epiphysis itself is tubular, and arches rapidly caudad to a point over the tectum, then curving more rapidly cephalad, between the hemispheres, is slung, as it were, in the membrane connecting them. The structure is like that of reptiles, varying much in different localities by the greater or less development of certain elements. In characteristic portions there is, first, the wall of connective tissue; seated upon this are slender cells, fibrous in character, which support small granular nuclei in several series, and centrally a larger nucleus beyond which the cell extends as a long narrow flagellum projecting into the cavity. The appearance is as though the single stalk supports nuclei of both sorts, though this may be an illusion. Nerve-fibres may be followed in the spaces between the cell-bases, extending in the direction of the axis of the organ, and passing into the larger nuclei. There can be no doubt of the nervous character of the organ.

"A blood-sinus closely invests the epiphysis, outside of which is a second investment from the dorsal sac which projects caudad to ensheath it. The walls of the dorsal sac consist of a single-layered epithelium with long cilia or flagella projecting into the lumen. Numerous plexiform diverticles also project into the cavity. The fibres from the epiphysis were traced, with apparent certainty, to the supra-commissura.

"Cephalad of the habenulæ, as well as immediately above them, the dorsal sac communicates with the third ventricle, the lateral ventricles being entirely distinct. Slightly farther cephalad the dorsal sac is shut off from a median portion which must be considered as homologous with the aula. Into this median portion the cavities of the lateral ventricles open, as usual, the only difference being that the aula is more elongated than usual, and the portæ are correspondingly enlarged. It has sufficiently appeared from the above that the dorsal sac is not a portion of the cavity of the prosencephalon, but of the diencephalon. It is not a new structure, but one found in reptilia as well, and pertains to the epiphysis."

In this connection was identified, apparently for the first time in fishes, a homologue of the hippocampus.

"The habena is imperfectly divided into two parts, a ventro-median portion, with smaller cells, giving rise to Meynert's bundle, and a cephalo-dorsal and ectal portion, of larger cells, giving rise to the tænia. The right habena is somewhat larger and is apparently chiefly associated with the fibres of the epiphysis."

The *hypoaria*, or caudo-lateral lobes of the cinereum, are less highly developed in Lepidosteus than in the sturgeon. They arise caudad of the chiasm as tuberosities of the lateral wall of the infundibulum dorsad of the ventral nidulus of large cells above mentioned. A diverticle of the infundibulum enters them, and this cavity expands to a spheroidal cavity. The cell structure is similar to that of the tuber. In Lepidosteus they extend much farther caudad, so as to reach the exit of the third nerve. A rather strong tract enters the caudo-mesad portion where it is becoming separated from the thalamus and passes toward the tract of the third nerve, passing Meynert's bundle, and apparently unites with fibres passing toward the cerebrum. If these fibres be compared with the fornix tract, they might seem to warrant the suggested homology of the diverticles of the third ventricle between the hypoaria with the mammillaria. This seems the more reasonable, inasmuch as there seems to be a homologue of the corpus geniculatum dorsad of them.

The *lobi optici* are very large and resemble those of reptiles in nearly every respect. Very large ventricles occupy their centres, and where these are confluent (Fig. 25) there is a curious pendant body on either side of the median line due to a lateral diversion of the median walls of the tecta, below their union with each other. This body, originally called fornix by Carus, may perhaps

retain the name suggested by Fritsch, *torus longitudinalis*, since it is free from the false homology involved in the other. The structure of this body is very simple, consisting of dense clusters of small cells like Deiter's corpuscles.

From the base of each optic ventricle there is a projection which has been called torus semicircularis. These lobes must be regarded as an inherent part of the mesencephalon, being provided with a slightly modified ventral accumulation of the cell-layer constituting the fourth of the above-mentioned layers of the tectum. The structures are those already familiar in reptiles, and called (rather unfortunately) by Rabl-Rückhard the *eollieuli*.

The roof of the aqueduct is thickened and thrust far forward under the optic lobes, or better, the optic lobes are thrust so far caudad that they over-arch the valve of Vieussens or *valvula eerebelli*. The presence in this body of the decussation of the fourth nerve is sufficient proof of the correctness of the homology.

In Lepidosteus the adhesion of the valve dorsally upon a forward tongue of cerebellum ventrad is considerable, but in Acipenser the ventral (cerebellar) portion is pushed forward and rolls cephalo-dorsad, fairly filling the cavity. The structure of this body, which may be called *volvula cerebelli* or *volvula*, is identical with that of the cerebellum proper.

The Cerebellum.—In the development of the cerebellum we have the most characteristic feature in the brain of the ganoid fishes and, at the same time, the peculiar modifications of the theme express the generic variations most distinctly. In the gars, where the whole brain is quite reptilian, the cerebellum is highly developed superficially, while in the sturgeon only a relatively small part is exposed, the remainder being packed in the cavity of the mesencephalon and the laterally enlarged fourth ventricle. In Lepidosteus the cerebellum may be divided into the following parts: first, a cephalic invasion of the mesencephalic cavity, more or less closely associated with the valve, constituting the *volvula* as above described; second, the median lobe or *vermiform lobe*, third, two *lateral lobes*; fourth, a posterior pouch or *bursa*.

In Scaphirhynchus the volvula is enormously developed and thrust far forward, completely obscuring the valve. Appearing first as a pentagonal projection from the inner (dorsal) surface of the (inverted) valve, it goes on increasing cephalad, till, rolling ventrad, it folds upon itself, turns caudad, carrying its median protuberance upon its (now ventral) surface, and passing somewhat dorsad to connect with the vermiform lobe. The central portion consists of white matter filled with enormous and beautiful branching Purkinje's cells, the lateral portions containing the Deiter's corpuscles. There is no bursa nor distinct cephalad diverticle, as in Lepidosteus, but the vermiform lobe remains a solid mass with its white matter mesad and dorsad and its granular layer laterad and ventrad to the end.

The Bony Fishes (*Teleostei*).—The discovery of Rabl-Rückhard[12] that the cortex cerebri is functionally absent and simply morphologically represented by a membranous pallium of fishes has opened the way for new studies in this neglected group. Great progress has been made in identifying homologies between the fish brain and that of higher vertebrates. The olfactory region is best studied in fishes because of the variability of the tuber and clues afforded by the manner in which the identical morphological relations are expressed under the varying conditions. Here, as in all other groups so far investigated, there are two distinct roots of the tuber. The radix lateralis is derived from the pero or external part of the tuber (that part composed of the glomerules and specific olfactory cells). This root passes along the ventro-lateral aspects of the cerebrum, at the line of union of the pallium with the axial lobe, and enters a special cluster of cells which has been homologized with a part of the hippocampus ("hippocampal nidulus").

The radix mesalis passes from the pes olfactorii and, even in the numerous cases where the tuber is removed by a long interval from the cerebrum, is always distinct from the preceding. It passes through the præcommissura. It has been shown that there are somewhat constant fissures upon the surface of the axial lobe and that the lobe is topographically subdivisible into subordinate lobes which differ in histological structure and fibrous connections. Thus the cephalic portion gives rise to the ventral peduncles which end in the hypoaria, while the dorsal part originates the dorsal peduncular bundles which pass to the midthalamus and there come into relations with the sensory niduli. The commissures of the cerebrum are difficult of interpretation. The great central bundle which connects the two axial lobes consists of three distinct portions, as described by Edinger and Bellonci; first, the præcommissura; second, decussation of olfactory radices; third, axial commissure (commissure of basal cerebral fasciculus, Edinger). In some cases feeble indications of a callosum have been recognized, as well as fibres from the "hippocampal nidulus," forming a "fornix" (Herrick).[14] The diencephalon is much modified in fishes and has received exceedingly divergent interpretations. The dorsal wall is frequently greatly reduced by the cephalic growth of the tectum opticum while its ventral aspect is increased by numerous expansions of a nervous or non-nervous nature. The non-nervous portions are essentially parts of the same system. The hypophysis and saccus vasculosus are both parts of a system of expansions of the ventral walls which are so thinned that only the thin, fibrous walls of the spongioblasts remain. These fibres have been described as nervous, but are undoubtedly remnants of the epithelium cells dragged out of the original position by distention of the walls. The saccus receives numerous vessels and is essentially a sort of plexus, while the axial part of the hypophysis is almost precisely similar and is in more or less direct communication with the former.

The hypophysis consists, in addition, of a mass of tubular vessels derived from the pharynx as in other groups. There are possibly nerve-fibres in the axial portion of the hypophysis, but most of the fibres which pass dorsad from it may be spongioblastic (gelatinous.) The epithelium of the saccus is ciliated. Caudad of the saccus are two small pouches which have been homologized by Herrick with the mammillaria. The great expansions back of the tuber cinereum known as the hypoaria or lobi inferiores are regarded by most authors as expansions of the base of the thalamus, but recently the view has been advanced that they represent (in part at least) the base of the mesencephalon which in other vertebrates is largely lost in the "saddle cleft."

In the base of the diencephalon of fishes the several decussations and commissures are unusually distinct. The commissura ventralis is the most ventral member of the system. The fibres arise in the tuber cinereum and form a true commissure. The commissura transversa is closely associated with the chiasm. Its fibres seem to spring from cells near the entrance of the cephalic branch of the optic tract into the tectum and may be associated with the anterior brachium opticum. A small but distinct bundle with similar course forms the commissura minor.

The commissura horizontalis, after forming a sharp loop across the median line, passes by a reverse curve through the nidulus ruber to the nidulus "corticalis" near the habena.

Meynert's bundle pursues the same course in fishes as in higher animals and serves as a valuable landmark. A possible tænia thalami connecting the diencephalon and prosencephalon was noted.

The dorsal surface of the thalamus gives rise (over the aula) to a remarkable pouch or dorsal sac which may extend far cephalad and is intimately associated with the epiphysis. It seems probable that the same structure exists in all vertebrates and forms the plexiform body, sometimes called paraphysis and in some cases mistaken for the epiphysis itself.

The habena is frequently well-developed and contains numerous small cells. It sends numerous spongioblast fibres into the tectum. The most remarkable external structure on the lateral surface of the diencephalon is

the geniculatum, which in its internal structure is peculiar. The ectal surface has numerous large cells like the peripheral cells of the hypoaria. These give rise to two fork-like processes which form a switch-station for the tracts. The interior is composed of similar cells in a great mesh-work of fibres. The ventral commissure enters it and thus suggests a connection with the brachia optica, while a contingent of fibres passes to the dorsal peduncle.

Although the optic nerves pass over the walls of the thalamus there is no connection directly with the cells of that region. The tracts divide at once into a cephalic and a caudal portion which pass severally to the cephalic and caudo-lateral portions of the tectum. The gray matter of the diencephalon will be further treated in connection with the mesencephalon.

The roof of the mesencephalon is composed of a greatly distended tectum opticum, while much of the central cinerea is crowded into the interior of the ventricle in the form of the torus. The latter is derived from the median part of the tectum and contains granules and cells. Its spongioblasts are connected with the tectum and are obviously simply the elongated walls of the displaced epithelium cells whose ventral ends have been crowded into the ventricular space. These slender remnants of the cell-walls (" gelatinous tracts ") are among the most important indices of the structural relations of the modified brain-walls. The tectum opticum is so complicated and difficult that no apology is necessary for giving in full the suggestions derived from a study of this organ in fishes.

The fibre-tracts are : 1. The optic fibres, entering from the cephalo-mesal and caudo-lateral aspects respectively. These tracts are part of the same continuous sweep of fibres from the optic nerve, which have been separated by the architectural necessities of the brain; their internal course is morphologically identical. 2. The fibres of the cephalic and caudal brachia which, after effecting cellular connections at their exit from the tectum (?), connect with a double commissural system (transverse and ventral commissures) as above described. 3. The radiation to the lemniscus derived from the ventral ganglionic series of the tectum and passing to the lateral aspects of the medulla. 4. Associated with the latter the fibres of the middle peduncles of the cerebellum (decussatio tegmenti) and probably also fibres to the third, fourth, and perhaps the sixth nerve niduli. There may also be among them commissural fibres. 5. The Sylvian commissure system whose fibres pass in a more or less complicated course from one side to the other, originating in the ectal reticulum of either side. 6. A system of fibres belonging to the category of gelatinous tracts, *i.e.*, connective fibres springing from the epithelium of the ventricular portion of the torus and passing to the ectal surface of the tectum.

The connective framework of the tectum is constructed on the same plan as that of the rest of the brain, and consists of a continuous epithelium with the base of each cell upon the ventricle and its summit at the periphery. The integrity of the series is greatly disturbed by the development of neuroblasts and their migration and the invasion of fibre-tracts, as well as by the great changes in position suffered as a consequence of the development of the cerebellum and volvula. The primitive simplicity is retained more perfectly in Amphibia (*Menopoma*, etc.). To all appearances, the nucleus of the epithelium cell divides without causing division of the cell, yet this is not certain. After passing the inner ganglion layer the walls collapse and form a thread which may enclose one or more nuclei and terminate at the periphery in a cell. These are conspicious in the young, but practically shrivel up with age. Between these cylindrical connective cells the neuroglia stroma, nerve-cells and fibres develop. The cells develop from the neuroblasts of the ventricular region and accumulate between the connective cells up to the level of the first fibre belt, forming a basal cellular zone. The upper portion becomes functional and some cells migrate toward the periphery. By the gradual thickening of the tectum the ganglionic layer is separated from the ventricular surface by an interval. It seems probable that only the outer portion of the dense zone of nerve-cells is functional, and it is only with these that a fibrous connection has been observed. The first layer of the tectum, beginning from the ventricle, therefore, consists of columnar epithelium cells whose protoplasm in the adult is more or less shrunken and whose nucleus may still remain distinct or may become imbedded in a thin layer of protoplasm adjoining the walls. The walls may collapse beneath the ganglion layer and there is frequently an intricate folding which produces a peculiar appearance in section, but Fusari has completely misinterpreted this appearance in Plate III. of his work.* The appearance of a brush-like radiation of fine processes is illusory and in perfectly prepared specimens, not too much dragged in cutting, the walls of the cylindrical epithelium cells can still be followed. Above this level the whole tectum becomes charged with a dense mass of gelatinous matter, giving it a homogeneous appearance. The (generally collapsed) walls of the connective cells pass directly toward the periphery and in some cases enclose nuclei with surrounding protoplasm. Whether these nuclei have simply retreated from the ventricular surface, or whether a single epithelium cell may have more than one nucleus is uncertain, but at the peripheral terminus there is always a small fusiform cell-like body.

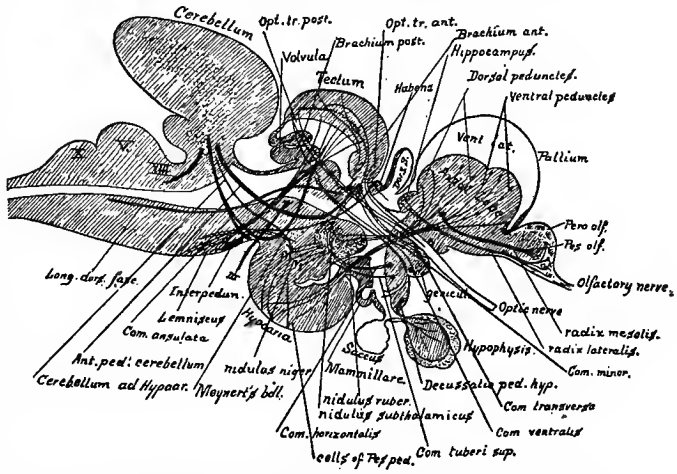

FIG. 457.—Diagrammatic Longitudinal Section of Fish-brain illustrating the Course of the Most Important Tract and Commissure. (From *Anatomischer Anzeiger*, vii., 13–14.)

These were apparently figured by Fusari as terminal expansions of ganglion-cell fibres in the plate above referred to.

It is only in well-preserved material that the distinction between the nuclei of the ventricular epithelium and the internal ganglion layer is obvious. A comparison with Amphibia shows that the same arrangement prevails there also. Each ganglion cell has its peripheral process, which passes into the ectal layer of the tectum and there divides dichotomously, mingling with the optic fibres to form a fine reticulum. This zone is perforated at intervals by the lemniscus and decussating cerebellar tracts, whose fibres collect ectad. In many cases actual communication between fibre and cell could be seen. But there is also a partial commingling of fibres of the next layer at some levels.

The fifth layer is a dense band filled with a homogeneous gelatinous substance, through which pass the fibres from the apical processes of the ental ganglion layer. It also contains sporadic cells of that layer as well as pos-

* Atti de Lincei Mem. cl. sc. fis. ecc. Ser. 4, Vol. IV. Intorna alla fina anatomia dell' Encefalo dei Teleostei.

sibly those forming the termini of the anterior branchium fibres; the sixth and seventh layers cannot be topographically distinguished with precision; the sixth is chiefly composed of transverse (sylvian commissure) fibres, while the seventh is the layer of optic fibres passing more or less obliquely caudad. Within these two layers is contained the ectal layer of ganglion cells of large size and with elongate processes. The apex process terminates in a strong fibre which divides dichotomously and gives off its ultimate branches to the reticulum. Careful study with high powers showed that these fibrils actually unite with or come into contact with the reticulum. The appearance of free termination, seen in Golgi preparations, seems to be unconvincing, especially in view of the imperfect conservation implied by that procedure. The basal processes of these cells turn cephalad and seem to enter the optic tract.

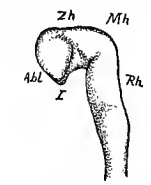

FIG. 458. — Youngest stage of Ichthyophis. *I*, infundibulum; *Abl*, optic vesicle; *Zh*, diencephalon; *Mh*, mesencephalon; *Rh*, metencephalon.

Amphibia.—The most notable recent additions to our knowledge of the amphibian brain are due to the efforts of Osborn, Burckhardt,[15] and Edinger.[6] The Gymniophona (subterranean amphibia) have been instructively compared with the salamanders, etc. Those amphibia which, like Ichthyophis, are meroblastic in development agree in the method of formation of the head with the Amniota in several aspects. We may conveniently refer to Dr. Burckhardt's figures of Ichthyophis. Fig. 458 is a lateral view of the youngest embryo. The infundibulum (*I*) is the front of the brain, which is somewhat curved ventrad. Comparing with this figure a nearly corresponding stage of the human embryo, as reconstructed from sections by Professor His, a marked similarity is obvious, Fig. 459. The greater elongation and differentiation of the human embryo is apparent and the infundibulum is less obviously the front by reason of the protrusion of the future optic recess. Fig. 460 is a later stage of Ichthyophis, in which the origin of the hypophysis is visible and the true nature of the cerebral vesicles as dorsal projections is very well exhibited. The saddle-cleft separating the metencephalon from the rest of the brain is greatly developed and still unclosed. In Fig. 461 the subsequent combinations are shown, and Figs. 462 and 463 give illustrations of the adult brain. The special development of a "temporal lobe" which may be compared with the "hippocampal rudiment" discovered by Herrick in fishes, is noticeable, though the connection of the præcommissure with the olfactory tubes described by Burckhardt must receive a new interpretation.

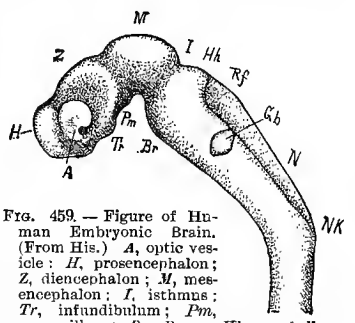

FIG. 459. — Figure of Human Embryonic Brain. (From His.) *A*, optic vesicle: *H*, prosencephalon; *Z*, diencephalon; *M*, mesencephalon; *I*, isthmus; *Tr*, infundibulum; *Pm*, mammillare; *Br*, Pons; *Hk*, cerebellum; *Rf*, roof of fourth ventricle; *Gb*, auditory vesicle; *N*, medulla; *Nk*, cervical flexure.

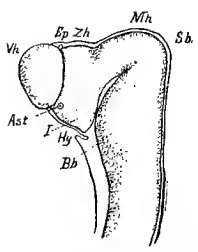

FIG. 460.—An Older Embryo of Ichthyophis. *Ep*, epiphysis; *Ast*, optic peduncle; *Sb*, mesencephalic flexure; *B b*, pons flexure.

The embryology of Ichthyophis shows that the nasal epithelium, Jacobson's organs, and other sensory patches of the roof of the mouth have a common origin, and it is but a step farther to identify them with the pituitary fundament as parts of a frontal sensory plate of the primitive vertebrate. Edinger recognized the existence of an occipital lobe in amphibia and observed the corpus callosum as described by Osborn.

Among the most stimulating papers of the last few years is Professor Osborn's[18] on the callosum. Respecting the Amphibia he says: "The cerebral commissures lie behind the foramina of Monro. They consist of an upper and a lower bundle. The former is much the larger. It passes upward and forward behind and above the foramen and gives the commissural supply to the dorso-medial portion of the hemispheres. It is the corpus callosum. The lower part is the anterior commissure. Its main division is the pars olfactoria, which supplies a part of the brain stem, the ventro-lateral portion of the hemispheres, and probably the olfactory lobes. Its lesser division, supplying the lower posterior part of the hemispheres, is the pars temporalis. The inner olfactory tracts arise near the anterior commissure, cross each other, and pass to the olfactory lobes."

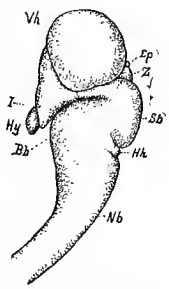

FIG. 461.—Embryo of a Still Later Stage.

The upper bundle of the callosum was found to develop at an early stage in the frog. The fibres of the anterior commissure appear somewhat later as a delicate thread beneath the callosum. A mechanical explanation of the fact that this order is the reverse of what occurs in mammals was suggested in what is called the primary and secondary positions of the callosum. In the primary position, Amphibia (and Fishes ?), this commissure lies in the floor of the primary fore-brain, a part of the brain-wall which is early developed, hence its development is as rapid as that of the anterior commissure. In the secondary position, mammalia, the callosum lies in the middle portion of the terminal plate, which is a later growth than the floor of the ventriculus communis, hence its late development. The existence of a fornix commissure was regarded as doubtful in amphibia, though certainly present in reptiles.

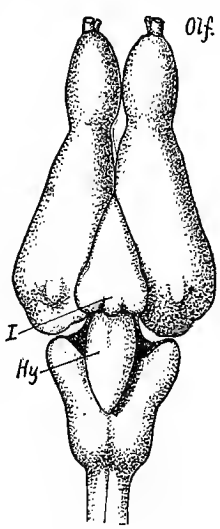

FIG. 462.

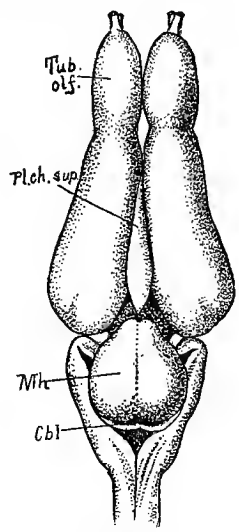

FIG. 463.

FIGS. 462 and 463.—Adult Brain of Ichthyophis.

A considerable dispute has grown up as to the propriety of applying the term callosum to the fibre-strands connecting the dorso-median portion of the mantle.

With the differentiation of a mantle from an axial portion of the cerebrum the dorsal system becomes more distinct and complicated, attention needs to be called to the fact that morphologically the precommissure, callosum, and hippocampal commissure are all parts of a

single system connecting homologous parts of segments of the dorsal part of the neuraxis. One may increase at the expense of another, or nearly supersede it, as is the case in the marsupials.

In 1888 Professor Osborn[16] devoted an extended paper to the amphibian brain. Some of his results are the following: There is a direct motor tract to the prosencephalon and diencephalon. A portion of the descending trigeminal tract passes through the cerebellum. The posterior (dorsal) longitudinal fasciculus sustains relations to the eighth, sixth, fourth, and third tracts. The nidulus of the oculomotor is connected with the post-commissure. A new sensory tract and nidulus common to the ninth, tenth, and seventh pairs of nerves was noticed. The size of the roof of the mesencephalon is in proportion to the functional perfection of the eyes. The cerebellum was regarded as intersegmental, and secondarily acquires a functional importance equivalent to that of other segments. The early constriction of the brain roof, which gives rise to the four vesicles, is for the accommodation of three nerve-fibre tracts decussating dorsally, viz., the supra- and post-commissures and the cerebellum, which in their primitive condition have a serial homology.

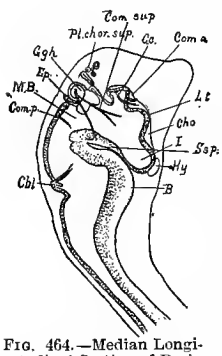

FIG. 464.—Median Longitudinal Section of Brain shown in Fig. 30. *Cc*, callosum; *Com. a.*, præcommissura; *Com. sup.*, supracommissura; *Pl. chor. sup.*, præplexus; *Ggh*, habena; *Ep.*, epiphysis; *Com. p.*, postcommissura; *Cbl*, cerebellum; *I*, infundibulum; *Cho*, chiasm; *Lt*, terma; *Hy.*, hypophysis; *Ssp*, "saddle-cleft;" *B*, pons.

In *Proteus* and *Menobranchus* the primitive epiblastic stalk of the optic vesicles is persistent.

The nerves of the third, fourth, and sixth pairs form a special system with no apparent homology or connection with the motor elements of the vagus or trigeminal systems.

The attempt to employ the cerebral commissures as landmarks of the chief morphological segments of the brain (Osborn[17]) has not been generally accepted, but has served to call out much useful discussion. Kupffer[18] attempts to show that the Amphibia have segments of the dorsal roof which are not developed in other classes, at least not to the same extent.

In Amphibia, Edinger identified the basal prosencephalic tract (ventral peduncle) which arises in the lateral and basal parts of the prosencephalon and passes to the diencephalon dorsad of the infundibulum, evidently forming anastomoses with cerebellar and other tracts. He also describes a homologue of the tænia thalami and an olfactory tract which, after crossing in the præcommissure, enters the diencephalon (?) and, doubtfully, a mantle bundle which decussates caudad of the chiasm. Two tracts (equivalent to Osborn's direct diencephalic tract) pass into the lateral aspects of the cord. The connection of the diencephalon with the cerebellum through prepeduncles is described, and it is apparent that the relations are the same as described by Herrick for Fishes.

The Brain of Reptiles.—The authors who have contributed most extensively to our knowledge of the reptilian brain are Stieda, Rabl-Rückhard, Edinger, Herrick, and Meyer. The prosencephalon was carefully described by Edinger[19] (1888), who discusses Lacerta agilis, Anguis fragilis, Emys lutaria, and Tropidonotus natrix. He divides the axial portion into a cephalic portion containing scattered cells and a caudal spheroidal portion which is called nucleus sphæricus. The origin of the peduncle tracts is in the axial lobe, and they divide in the thalamus, one to enter the nidulus of the thalamus, while the ventral portion passes on into the medulla. The figures, however, leave open the possibility that the ventral peduncle communicates in this case, as the writer has shown in Fishes, with the middle peduncle of the cerebellum.

The dorsal cortex of the median wall of the hemisphere is considered homologous with the cortex of the cornu ammonis, and a portion of the median wall devoid of cortex is said to represent the fornix ridge. Edinger says explicitly that the cortex first appears in Reptilia, though we now know that it is represented in Dipnoi and Amphibia.

A callosum and fornix bundle are recognized much as they were by the writer. Aside from the fornix region an occipital region and a dorsal region are distinguished, which latter is supposed to communicate with the olfactory. An intermediate cell layer is also mentioned.

The writer[20] published one year later a brief account of the alligator, in which many of the above points were independently observed. The mistake of Wiedersheim and Rückhard in supposing the olfactory bulb to be absent is corrected by reference to the young brain, in which the tuber still adheres to the brain.

Distinct callosum, fornix, and tænia thalami were observed, and also a bundle corresponding to that called by Edinger "*Bündel der sagittalen Scheidewand.*" The several commissures are found to occupy the same relative position as in other Vertebrates. The remarkable olfactory fossa, a depression found in all Reptiles and in the Opossum, is noticed for the first time.

"Three distinct kinds of cells can be detected in the mantle, one characteristic of the superior and anterior regions, a second of the occipital, median, and posterior-lateral regions, and a third about the ventro-basal region or hippocampus.

"The natural division of the cerebrum into an axillary and mantle portion is very convenient for the purpose of description of the nervous elements. Attention is again called to the reason for regarding these two regions more closely related than either is with the diencephalon. The corpus striatum, as such, does not exist in the alligator, but the major part of the cerebrum consists of what Rabl-Rückhard called axillary lobes (*Stammlappen*). The axillary lobes consist of a rather homogeneous mass of cells, and has a contour similar to that of the entire hemispheres, but is covered by a mantle which embraces it on all sides except behind, and is separated from it on all sides except antero-inferiorly by the ventricle, which is exceedingly narrow. The axillary lobes are, therefore, the immediate cellular envelopes of the direct extension of the peduncles. The mantle portion is exceed-

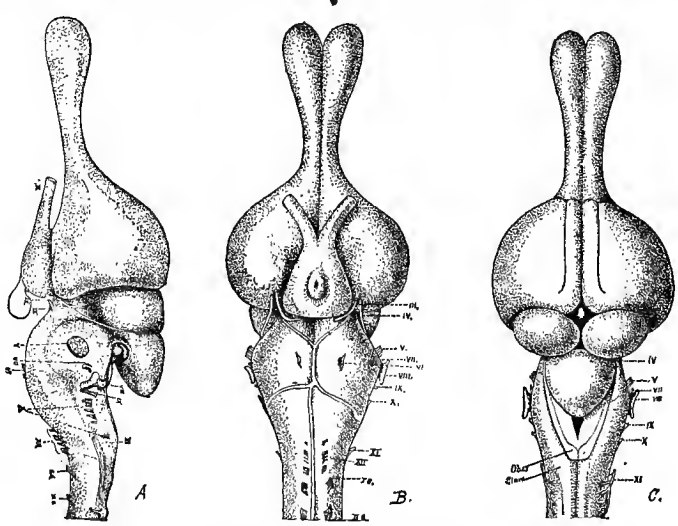

FIG. 465.—*A*, *B*, *C*, Three Views of the Brain of a Young Alligator.

ingly thin, and presents little opportunity for variety in structure. There is, however, a marked diversity in the cellular elements entering it.

"From analogy these varieties of cells may be assigned to motor, psycho-sensory, and special olfactory functions respectively. The axial lobes likewise have two sorts.

"The pyramidal cells which were first above mentioned stain deeply, have small nuclei, and have a long apex-process, generally directed obliquely toward the periphery, and several basi-lateral processes. No central basal process such as described by Meynert was seen. These motor-cells can be traced into connection with the basal prosencephalic tract (continuations of the peduncles). Indeed, similar cells can be followed to the diencephalon. The second variety of cells is flask-shaped or balloon-shaped, and has a slight power of precipitating stains; and is further characterized by the large, clear nucleus, or perinuclear space. Such cells are distinctive elements over the posterior and median parts of the cortex. Especially constant are they in the median wall.

"The great bulk of the axial lobes—that portion which protrudes into the ventricle—is filled with similar flask cells, but these are curiously clustered in groups of two or multiples of two. The evidence that these cells are undergoing rapid increase by fission in this young animal is very conclusive. All stages of the process may be ob-

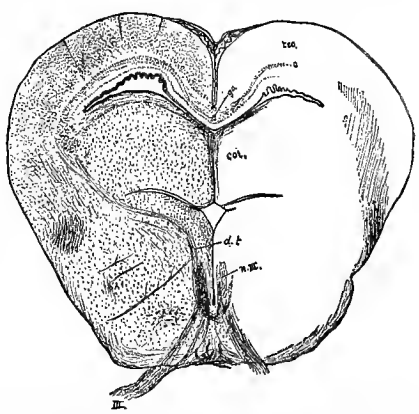

Fig. 466.—Cross-section of Optic Lobes of Alligator at Exit of Third Nerves. *col.*, Colliculus; *tec.*, tectum; *g.c.*, large cells of mesencephalic root of the fifth nerve; *n. III.*, nidulus of the oculo-motor; *d.t.*, tract from tectum passing adjacent to the nidulus.

served. It may be suggested that, if in the case of young animals this part of the brain is most actively multiplying cells, it is possible that the growth of the mantle (in which there is little material for rapid growth) may be in some way associated with this proliferation of cells, resulting in the increase of the mantle from its margins, as though the material were pushed up around the margins of the ventricle by rapid growth within.

"The connection of this portion of the axial lobes of the cerebrum seems to be with the superior or sensory longitudinal tracts of the peduncles. In addition to the tracts above mentioned, the tænia thalami, springing from the basal region and passing to the habenulæ, form a sensory link between the thalamus and the cortex. It is noticeable that the cells associated with this tract, even in the thalamus, are of the flask variety."

Four areas of the mantle were distinguished, and the variety of cells contained in each seemed to substantiate the theory that the pyramidal cells are motor and the flask cells sensory. "One cell-cluster, which occupies a relatively small area anteriorly, but increases caudad, occupies the lower median portion of the mantle. It consists of flask-like or sensory cells with fibres, which can be traced to the tract leading directly ventrad to the ventral median portion of the posterior part of the brain, *i.e.*, the hippocampal region, and seems to embrace the continuation of the olfactory tract."

The above indicates that the writer identifies the homologue of the hippocampus differently from Edinger, and relies on the course of the olfactory fibres as a guide, as Burckhardt has since done.

The existence of communicating tracts between the tectum opticum and the oculo-motor roots was noted. See Fig. 466.

In 1881[21] the writer published several contributions to the neurology of Reptiles. The free caudo-ventral portion of the cortex is definitely homologized with the hippocampus and two distinct portions are distinguished. The axial lobe is divided into two portions. The caudal one (n. sphæricus of Edinger) is coiled upon itself by the backward revolution of the hemisphere and is called the occipito-basal lobe, while the cephalic portion, receiving the peduncular tracts and probably representing the striatum, is known as the central lobe.

The cortex is aggregated in specialized regions, called the frontal, parietal, fronto-median, and intra-ventricular respectively.

The pre-commissure consists of three parts, one of which passes to the pes of the olfactory, another to the lateral regions of the hemisphere, and the third to the occipito-basal lobe. The callosum and tænia thalami are also described.

The existence of two commissures in the region of the epiphysis is noted, one being the pre-commissure, the other the commissure of the habena. Attention is called to the fact that the projecting plexus (conarium of European authors) has been frequently mistaken for the epiphysis (Zirbel).

Meyer[23] devotes an extended paper to the reptilian brain, but finds it necessary to rename many of the organs. He describes the radix lateralis as extending from the olfactory pero to the occipito-basal lobe (his "nucleus sphericus"). Much difficulty in construing the olfactory region would be removed if the pes olfactorii were recognized as a part of the hemisphere. The subdivision of the mantle into a number of distinct cell-groups is recognized. The median wall is called septum pellucidum, but the author finds no commissural fibres connecting the pallium of the two sides.

If it were present it could not represent the callosum, which, he claims, must arise in a late stage of development and form a secondary connection between the hemispheres. The writer has abundantly demonstrated the existence of a callosum in the sense employed by Osborn in other reptiles, and sees no reason why the period at which the fibres appear should influence the homology, especially as we know almost nothing of the period when they appear in Reptiles. Nothing is more probable than that a strongly developed mass of commissural fibres should create a place for themselves apparently outside the septum in which they originate.

The Brain of Birds.—The most important contribution which has yet appeared in this department is that prepared by Mr. C. H. Turner,[22] under the direction of the writer, in 1891.

Compared with other Sauropsida the avian brain is quite large and is remarkably compact. The large prosencephalon entirely covers the diencephalon, and may cover rhinencephalon and mesencephalon. Although the compactness of the brain, the highly developed cerebellum and ventrally and laterally revolved optic lobes give to the bird-brain a habitus peculiarly its own, yet it is, after all, but a modified reptilian organ. Mr. Turner shows that a careful use of brain measurements and proportions offers valuable aid in classification.

The avian prosencephalon is large, but unconvoluted. The epencephalon is well developed and transversely convoluted. From the introduction of the class Aves until now there has been a gradual retrograde evolution of the avian rhinencephalon. In the lowest type of birds the rhinencephalon is double, and projects beyond the cephalic extremity of the prosencephalon; in the highest type it is single and does not project. In the lower types of bird-brains the optic lobes are only partially covered by the prosencephalon. During the evolution of the class Aves and the differentiation of the

families in it the dorsal and lateral portions of the avian prosencephalon have grown caudad much more rapidly than the ventral and mesal portions. This has caused the caudal portion of each cerebral hemisphere to revolve toward the meson, and, at the same time, to cover the optic lobes. The avian brain has great toxonomic importance. So far, at least, as major groups are concerned, a classification based upon it agrees in all essentials with those based upon a careful study of all the structural elements. There is a distinct callosum in addition to the precommissure. There is a fibre-tract connecting the mesal division of the mantle with the optic lobe of the same side. There is a correspondence throughout the class in the distribution of cell-types. The mesal division of the mantle contains fusiform cells only. The lateral division contains pyramidal cells only. The striatum contains cells of both types. There is a proliferating area in the axial lobe where small cells are produced. There is an involution of cortex in the occipital region of which there is no external indication. Birds are pre-eminently seeing animals, and all parts that appertain to vision are developed to a great degree. The optic nerve is the largest of the cranial nerves, and the optic lobes are complexly differentiated bodies. Even the third, fourth, and sixth nerves are relatively larger than the corresponding nerves of the mammalian brain.

Mammalia. Minute Anatomy of the Spinal Cord.—Professor Golgi, of Pavia, by means of the method which bears his name, made out the following points, upon which recent investigations have been founded:

1. All the nervous cells of the cord have but one nervous process. (That is, only one process which gives origin directly to a nerve-fibre. Opinion differs greatly as to whether the other (protoplasmic) processes convey or receive nervous stimuli or act simply as nutrient roots.)

2. The protoplasmic (shorter, branching) processes do not give rise to nerves but are distributed to blood-vessels and glia-cells.

3. Nerve-cells differ greatly in size and form and method of branching of the protoplasmic processes, but these variations are not especially significant.

4. More essential characters are furnished by the behavior of the nervous branch, in accordance with which we may distinguish two types of nerve-cells: (*a*) Such as have an axis-cylinder which soon subdivides and produces a reticulum; (*b*) such cells as send out an axis-cylinder which maintains its integrity in spite of producing a few lateral branches. Cells (*a*) are found in the dorsal cornua and substantia gelatinosa, cells (*b*) in the region of the motor-root (ventral cornua).

5. In the cinerea of the cord there is a diffuse reticulum of fibres which is continued into the medulla and forms a communication between all parts of the gray matter. In the cord this reticulum is formed of the fibres of the dorsal roots and nervous processes of the sensory cells, as well as of branches of fibres from the motor-cells, and similar cells of the dorsal cornu and from small branches from the fibres of the various tracts.

6. In the cord nerve-cells of very different value are promiscuously scattered.

7. The second type of cells (sensory), with divided axis-cylinders, is found in the cells of the substantia gelatinosa, a considerable number of the cells of the dorsal cornu proper, a few irregularly arranged cells of the marginal layer between the two cornua, and a few which are scattered in the ventral cornu.

The motor type of cells is found represented by the majority of the cells of the ventral cornu, a few cells of the dorsal cornu, and cells of the intermediary zone, especially those adjacent to the lateral bundles.

The majority of the cells of the ventral cornu send their axis-cylinders into the ventral column or the ventral root, while a considerable number pass through the ventral commissure into the white bundles of the opposite side. A few cells send their processes into the lateral and ventro-lateral columns.

In the ventral commissure three kinds of fibres cross to the opposite side: those of the cells of the dorsal cornua, those from cells in the ventral cornua, those from the zone between the central canal and the lateral columns. There seems to be a doubt in the mind of Golgi whether the cells actually pass into the columns of the opposite side or simply divide to form a reticulum. The fibres of the sensory nerves, after entering the spinal cord, subdivide like the axis-cylinders of cells of the second type.

To these important statements the following were added by Ramón y Cajal, who used the same methods and came to similar conclusions as Golgi, quite independently of the latter:

(1) The nerve-fibres of the sensory roots divide after entering the cord into an ascending and descending branch, associated with the fibres of the dorsal cornua.

(2) Cajal believes that the free tips of the nerve-fibres

and their branches end free instead of forming a reticulum.

(3) In accordance with the above, nervous influence is transmitted by contiguity or contact and not by continuity of the paths.

Professor Kölliker, in an admirable monograph published in 1891, reports the following results:

(1) The sensory root-fibres divide, as described by Cajal, the branches lying in the dorsal columns are superficially in the substantia gelatinosa in the marginal zone. Some of these branches may be followed four to six centimetres, while others turn entad and end in free tips.

(2) No instance of direct connection between the fibres of the dorsal roots and the cells of the cord has been observed.

(3) All sensory longitudinal fibres of the columns give off collaterals, which subdivide and end free in the gray matter. These are particularly numerous in Clark's column and the marginal region of the gelatinosa.

(4) The motor root-fibres spring from large and small

cells of all parts of the ventral cornua in the form of a simple axis-cylinder. (There may be small branches.)

(5) The ventral and lateral columns of the cord are composed in part of fibres which arise in all regions of the cord. These cells frequently give off from their fibres more or fewer lateral branches, which end free in the gray matter.

(6) All, or nearly all, the conducting fibres of the ventral and lateral columns give off collaterals which enter the gray matter of the ventral cornu and the ventral part of the dorsal cornu and terminate free, and many of the fibres themselves bend at a right angle and end in the same way.

(7) The ventral commissure consists of (*a*) nervous processes from cells of the cinerea of all regions, which, after crossing, are continued as longitudinal fibres of the ventral and ventro-lateral columns, (*b*) crossed collaterals of the ventral and lateral columns, and (*c*) crossed protoplasmic processes of a part of the cells of the ventral cornua.

(8) The dorsal commissure is composed of (*a*) crossing collaterals of sensory root-fibres, (*b*) possibly the crossing of collaterals of the dorsal part of the lateral columns.

(9) Nerve-cells of three sorts, (*a*) motor, (*b*) cells of the columns, and (*c*) other cells whose nervous processes do not extend beyond the gray matter but simply subdivide within it (dorsal cornu).

(10) Protoplasmic processes subdivide minutely and ramify in various parts of the gray and white matter, but do not give rise to nerve-fibres or anastomoses.

(11) The glia-cells are formed from the elements of the medullary plate, and are either primary or secondary, the former remaining as the ventricular epithelium.

Professor Kölliker, accordingly, agrees with Golgi that the protoplasmic processes are solely nutritive, never exerting a nervous influence over adjacent structures. The influence exerted by one neuron upon another is purely by contact, not by continuity. Voluntary motion is produced by the effect produced by pyramidal fibres upon the motor cells of the ventral cornua, a process which is facilitated by the collaterals and terminal brushes of the former forming a net-work around the latter and thus coming in contact with the cell.

Sensory impressions are conveyed through the dorsal root-fibres, which ascend to the medulla and thence by undiscovered paths to the brain. Reflex reactions are explained by the passage of collaterals of the dorsal root-fibres to the cells of the ventral cornu.

MINUTE ANATOMY OF THE CEREBELLUM.—The most important recent additions to our knowledge of the histology of the cerebellum are derived from applications of the Golgi method to embryos of various groups of Vertebrates. The most significant papers are those of Golgi, Cajal, and Kölliker. It will be remembered that the cerebellum contains four layers, which, beginning at the periphery are (1) the molecular layer, containing superficial fibres; (2) the layer of Purkinje cells; (3) the granular layer; (4) the white matter or axis-cylinder layer.

(1) Golgi was the first to clearly prove the existence in the molecular layer of small ganglion cells. These cells are of variable form and give off "axis-cylinder" processes, which lie chiefly transverse to the convolutions, and which, in the deeper cells, give off perpendicular fibres which, according to Cajal, form a basket-like envelope for the Purkinje cells. The peripheral cells are smaller, and are similar to other bipolar cells. Gierke had observed what he called neuroglia envelopes of the Purkinje cells, and it is not impossible that these "basket cells" may be of this nature, but the unanimous opinion of those who have studied them by the new methods is that they are nervous, and that the processes which envelop the Purkinje cells do not actually unite with the latter but simply are contiguous to them.

(2) Purkinje's cells are shown by this method to have an extraordinarily abundant supply of processes similar in structure to the protoplasmic processes. These processes ramify in the molecular layer, and, although they may reach the surface, do not anastomose or connect with the pia, the blood-vessels, or other fibres. These fibres are chiefly confined to one plane, *i.e.*, transverse to the convolutions. The axis-cylinder process may give off a few lateral processes, but continues into the white zone.

(3) The granular layer contains two kinds of cells: (*a*) The small nerve-cells are scattered throughout the layer and give rise to a number of short, much-branched protoplasmic processes and to one long-axis cylinder. The latter passes between the Purkinje cells, and, after penetrating the molecular layer, divides into two branches, which extend parallel to the surface and in the plane of the gyri for some distance. It would seem that these cells are the ones which migrate from the surface at a late period of embryonic life, as described by Herrick (see next article). (*b*) The larger cells of the granular layer are not numerous and are irregularly distributed. The "axis cylinder" branches very profusely.

The medullated fibres form a dense layer beneath the Purkinje cells, while others pass into the molecular layer

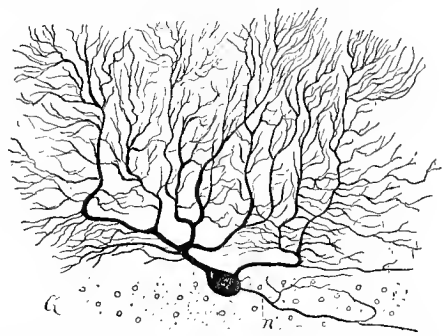

FIG. 469.—A Single Purkinje Cell (by Golgi's Method). *n*, Axis-cylinder process passing into the granular layer (*G*).

and subdivide. Such fibres also occur in various parts of the molecular layer. The connections are as yet obscure.

TYPES OF CORTICAL CELLS.—Various observers substantiate Golgi's statements that sensory and motor (psycho-motor and psycho-sensory) cells differ in the nature of their axis-cylinder or nervous process. Martinotti especially claims that the ganglion cells communicate by a single nervous process with the axis-cylinder, while the protoplasmic processes do not connect directly or indirectly with the nervous fibres but tend to pass to the blood-vessels and surfaces. Two sorts of ganglion-cells are recognized: one in which the nervous process divides and forms a network or neuropilem, the other in which there is direct connection with a corona radiata fibre. Herrick has attempted to distinguish sensory and motor cells by other methods. In those regions ventrad of the rhinalis fissure the cortex is composed of cells whose processes subdivide to form a dense neuropilem or nerve-felting in the so-called neuroglia layer entad of olfactory fibres from the radix lateralis. This type of cell corresponds with the second type of Golgi (Fig. 472, *s*).

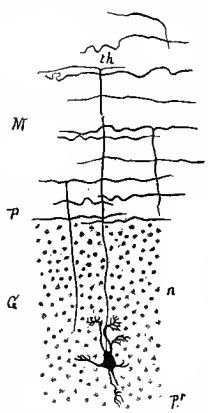

FIG. 470. — One of the Smaller Cells of the Granular Layer. *th*, Bifurcation of axis cylinder (*n*); *pr*, protoplasmic process; *M*, molecular layer; *P*, layer of Purkinje cells; *G*, granule layer.

The motor cells are pyramidal with a peripherad process much more conspicuous than the remainder. Regions known to be sensory in function contain a large number of cells of a different type; the form is rather flask-shaped than pyramidal, and the nucleus is clear and spherical. The delimitation of areas is very incomplete, and both types of cell are to be found in nearly all parts of the dorsal cortex, though the second (æsthesodic) variety is most abundant over the occipital region. The same writer has shown that in reptiles and other vertebrates lower than mammals the distinctions between the two types of cells is very clearly seen.

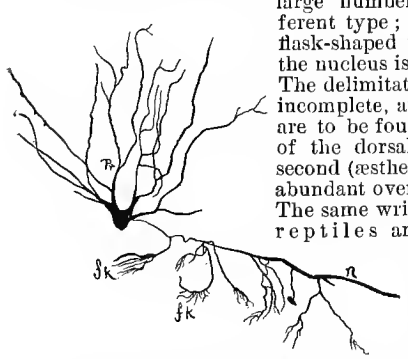

FIG. 471.—Basket Cell from Molecular Layer. *Pr*, Protoplasmic processes; *n*, axis cylinder; *fk*, basket-like envelope of the Purkinje cells.

FISSURES OF THE CEREBRUM. Dr. J. D. Cunningham,* in the "Memoirs of the Irish Academy of Science" bearing his name, gives an extended account of the comparative development of the surface anatomy of the cerebral hemispheres. We condense from this work the following statements:

Complete Fissures ("Total Falten").—The transitory fissures which appear in an early period of the development of the hemispheres are distinguished by the fact that they are a result of a series of deep infoldings of the thin cerebral wall and form shelf-like projections into the ventricles.

Under normal conditions none of the fissures which appear on the lateral aspects of the hemispheres persist in the adult, though in the ape two at least are persistent. Upon the mesal aspect, on the contrary, the choroid, a portion of the arcuate, and sometimes the parieto-occipital with part of the calcarine fissures persist. The choroid and arcuate appear as early as the fifth week. The choroid fissure occupies the lowest limit of the mesal wall, reaching the porta, cephalad, and extending caudad nearly to the extremity of the temporal lobe. Though not at first occupied by blood-vessels, and therefore not formed by them, its walls do not develop into nervous tissue but remain epithelial and are occupied by this preplexus. The fissura arcuata (*Ammonsfurche* of Mihalkovics) makes its appearance on the mesal face of the hemisphere at a higher level than the choroid fissure, and while it extends, like the preceding, into the temporal lobe, it also passes cephalad into the frontal region. That portion of the hemisphere lying between the two fissures mentioned is termed the *arcus marginalis*, in connection with which are formed the callosum, the gyrus dentatus, and the fornix.

The caudal part of the fissura arcuata is retained in adults as the hippocampal fissure, and gives rise to the elevation in the floor of the descending cornu known as the hippocampus major.

Dr. Cunningham does not agree with Mihalkovics and other writers that the cephalic part of this fissure produces the callosal fissure, but regards this portion as transitory.

The remainder of the complete fissures are transitory. The mesal wall of the hemispheres being thicker than the outer the transitory fissures there first appear. They may appear as early as the eighth week, and reach a high degree of development only after

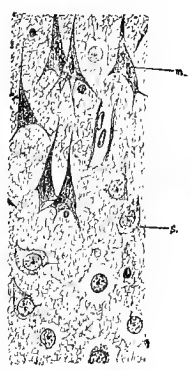

FIG. 472.

FIG. 473.

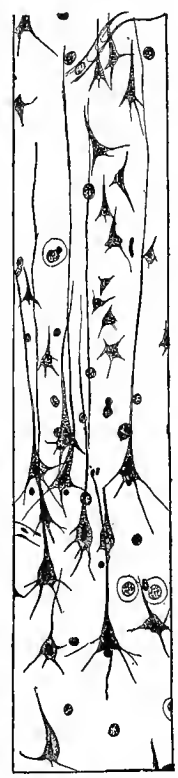

FIG. 474.

FIGS. 472, 473, and 474.—Types of Cortical Cells (all from the Opossum). Fig. 472, *m*, motor (above), and *s*, sensory (?) cells (below). Fig. 473, sensory (?) cells. Fig. 474, pure motor cells.

* Contribution to the Surface Anatomy of the Cerebral Hemispheres, J. D. Cunningham, Cunningham Memoirs of Royal Irish Academy, vii.

the tenth week. Their maximum development is reached between the periods when the fornix and callosum appear, *i.e.*, near the beginning of the fifth month.

On the mesal aspect of the hemispheres the transitory fissures, which vary in number, radiate from the arcuate fissure toward the free border of the hemisphere, and others, lying between them, but not connecting with the arcuate fissure, appear near the margin. The usual number on each hemisphere appears to be eight.

The primitive fissures which bound the cuneus are the precursors of the calcarine and parieto-occipital fissures. As the wall of the cerebral vesicle thickens, and the hemisphere elongates, the stellate fissures become detached from the arcuate fissure and gradually disappear.

Upon the outer aspect the arrangement of the fissures is also radial, with the Sylvian fossa as the centre, but these fissures usually do not reach the fossa. There is frequently an additional fissure occupying the place of the future Sylvian. In some cases the precursor of the calcarine is carried horizontally around the occipital pole, appearing on the lateral surface as an external calcarine fissure.

It is regarded probable that under abnormal conditions, as when the callosum fails to develop, the transitory fissures may persist to a certain extent. The fact emphasized by Sir William Turner, that in *Macropus*, where the callosum is rudimentary, the radiating fissures resemble those of an immature human brain, is at least suggestive that the development of the callosum has some effect on the disappearance of these fissures.

Dr. Cunningham fully agrees with His and Kölliker that the occipital lobe is due to a general growth and not a local out-pouching of the hemisphere; its peculiar form is due to the transformations produced by axial flexures —especially the pons flexure. This backward thrusting of the posterior part of the hemisphere is chiefly responsible for the preservation of the precursory calcarine and parieto-occipital fissures. The temporary fissures are in all probability peculiar to primates, and appear prior to the appearance of a distinct occipital lobe.

The parieto-occipital and calcarine fissures form upon the mesal aspect of a posterior part of the adult hemisphere a >— shaped figure. The stem is directed obliquely ventrad and intersects the gyrus fornicatus. The parieto-occipital fissure forms the more direct continuation of the stem, and continues on the ectal surface as the external parieto-occipital fissure. The calcarine branch passes toward the occipital pole. The stem is called the anterior calcarine fissure. The apex of the cuneus gives off two deep annectant gyri—the gyrus cunei and anterior cuneo-lingual gyrus. The gyrus cunei forms a barrier between the parieto-occipital fissure and the stem, while the gyrus cuneo-lingualis anterior separates the stem and the posterior part of the calcarine fissure.

The calcar (hippocampus minor) is formed wholly by the stem or anterior calcarine fissure.

In apes the calcarine fissure is deep and much more stable than the parieto-occipital. In the chimpanzee the gyrus cuneus is on the surface (a condition found in 3.9 per cent. of human brains), while in the orang and gibbon the cunei may be on the surface or at the bottom of the fissure. The gyrus cunei is never absent. Cunningham believes that the whole calcarine fissure of anthropoids corresponds to the "stem" of the human calcarine, or rather, the whole length of the precursor of the human calcarine is the equivalent of the ape calcarine. The posterior calcarine of man is of later origin and takes the place of an abolished portion of the original fissure. The cuneus of the ape does not have the same morphological value as that of man. Only the cephalic part is present in the ape, the caudal part is absent or blended with the gyrus lingualis. In the ape the entire length of the calcarine fissure is on the tentorial face of the hemisphere.

The posterior calcarine fissure is distinct from the "stem" in origin, the latter being a "complete fissure" and having unbroken continuity of existence with the fore-part precursor.

The occipital and parietal indices are the distances along the mesal margin of the hemisphere intercepted by the intersection of the external parieto-occipital fissure and the fissure of Rolando respectively, in the first case measuring from the occipital pole, in the second from the parieto-occipital intersection, both these distances in terms of hundredths of the entire length along the dorsal margin of the hemisphere.

For the human brain the following averages are given:

5½ to 6½ months..	O. index,	18.8;	P. index,	28.5.
6½ to 7½ months..	"	18.6;	"	24.7.
7½ to 8½ months..	"	20.7;	"	24.1.
Full time fœtuses,	"	20.8;	"	25.7.
First 12 months..	"	22.3;	"	25.6.
4 to 5 years.....	"	23.2;	"	24.2.
11 to 15 years....	"	20.8;	"	27.4.
Adults.....	"	21.2;	"	25.5.

For apes the following table is given:

Orang.....O.	index,	23.2;	P. index,	21.3.
Chimpanzee.....	"	24.2;	"	19.9.
Hamadryas.....	"	29.5;	"	20.5.
Cynocephalus....	"	29.7;	"	22.6.
Mangaby.....	"	30.5;	"	24.1.
Macaque.....	"	31.0;	"	19.0.
Cercopithecus....	"	32.9;	"	19.0.
Cebus:.....	"	33.1;	"	20.6.

The low parietal index and high occipital index are instructive features. In low apes there is an enormous increase in the occipital portion of the border; whereas, in the high apes, the amount of increase is smaller. The relative shortness of the parietal border in high apes is due to the relative increase of the occipital and frontal borders. In low apes the reduction of the parietal portion is entirely due to the great size of the occipital lobe.

The following summary is reproduced verbatim:

1. At an early period in the development of the cerebral hemisphere a series of deep infoldings of its thin walls make their appearance. On the exterior of each hemisphere these show in the form of sharply cut linear fissures.

2. Certain of these fissures are permanent; the great majority are transitory.

3. The transitory fissures, with two exceptions, have disappeared by the time the corpus callosum is fully formed.

4. A deficiency of the corpus callosum is associated with a persistence of the temporary fissures.

5. The temporary fissures indicate an important stage in the growth of the cerebrum, and are apparently associated with the mapping out of the occipital lobe.

6. A quadrupedal pause in the growth of the cerebrum brings the skull capsule into antagonism with the growth of the hemispheres, and, in consequence, the wall of the cerebrum is thrown into folds. These folds disappear as the occipital lobe assumes shape, owing to the expansion of the cranial cavity, and a restoration of growth harmony between skull and brain.

7. Consequently it is only in Primates, which alone possess well-developed occipital lobes, that transitory infoldings of the cerebral walls in all probability exist.

8. The two transitory fissures which do not disappear before the full development of the corpus callosum are: —(*a*) the external calcarine, and (*b*) the external perpendicular fissure of Bischoff. In point of fact the latter fissure does not appear until after the full development of the corpus callosum.

9. The external calcarine fissure produces an infolding of the outer wall of the posterior horn of the lateral ventricle, which presents the same direction, and lies immediately opposite to the true calcarine infolding, or the calcar avis.

10. The fissure corresponding to this in ape is, as a rule, permanent, and in some species its anterior end forms in the adult a bulging on the outer wall of the ventricle.

11. The external calcarine fissure disappears before the sixth month of fœtal life in man.

12. The external calcarine fissure is present on the outer surface of the fœtal cerebrum from the beginning of the fifth month to the end of the sixth month.

13. It is a complete fissure and corresponds to the "Affenspalte" on the ape's brain.

14. The "Affenspalte" on the ape's brain is also a complete fissure, and presents a well-marked bulging on the outer wall of the posterior horn of the ventricle; but, unlike the external perpendicular fissure of the human fœtus, it is permanent.

15. Certain fissures, therefore, which are complete and temporary in the human brain, are complete and permanent in the ape's brain.

16. The complete permanent fissures in the human are:—(a) the fore part of the calcarine; (b) the hinder part of the fissura arcuata; (c) in many cases the parieto-occipital; and (d) in some cases the mid-collateral. The Sylvian fissure is not a complete fissure.

17. Of the fissura arcuata the hinder part alone is preserved as the fissura hippocampi. The fore part, which is generally supposed to be retained as the callosal fissure, is in reality obliterated.

18. Synchronous with the appearance of the radial transitory fissures on the mesal face of the hemisphere two fissures appear, which lie in series with the former and occupy the ground afterward held by the parieto-occipital and calcarine fissures. These may be termed the precursors of these fissures.

19. The precursor of the parieto-occipital fissure sometimes shows an unbroken continuity of existence with the parieto-occipital fissure of the adult brain. In other cases it is obliterated, and its place is afterward taken by a secondary sulcus, which attains, however, a very great depth.

20. In the adult brain the parieto-occipital fissure, even in its complete form, does not form any eminence on the inner wall of the posterior horn of the ventricle, because it does not extend downward as far as the cavity. Above its lower end the hemisphere is solid.

21. The posterior end of the calcarine precursor is in every case obliterated, and the anterior part retained. The extent of the part obliterated varies considerably in different brains.

22. The anterior preserved portion of the calcarine fissure forms the "stem" of the >— shaped fissural arrangement on this part of the hemisphere, and its hinder part corresponds to the calcar avis.

23. In the place of the hinder portion of the calcarine precursor, which is obliterated, a secondary furrow appears. This may be termed the posterior calcarine sulcus.

24. The posterior calcarine sulcus is formed in two pieces which run together and also form the "stem." In this way the entire length of what, in anatomical language, is called the calcarine fissure is formed.

25. The posterior calcarine sulcus is not a complete fissure.

26. In the ape the entire length of the calcarine fissure is represented by that portion of the fissure which in man is termed the "stem," and by that alone. The posterior calcarine sulcus does not exist in any form in the apes.

27. The cuneus, therefore, has a different morphological value in the apes and in man. In connection with this compare the abnormal human hemispheres. These exhibit certain conditions which approximate to those present in the apes.

The Fossa and Fissura Sylrii.—The sign of the Sylvian depression appears at the end of the second month of development. Dr. Cunningham summarizes his investigations as follows:

"1. As growth proceeds the outline of the Sylvian fossa changes considerably. At first nearly circular, it elongates in a vertical direction and then backward on itself, and assumes a triangular outline.

"2. The high prominent mantle-border or rim which surrounds the depression is divided by intervening angles into four sections, viz.: The *temporal*, or lower; the *fronto-parietal*, or upper; the *frontal*, which is formed by an opening out and flattening of the primitive single anterior angle; and an *orbital*, or front portion.

"3. Each of these portions of the bounding rim acts as an independent line of growth, and consequently, in course of time, four opercula grow over the Sylvian area so as to enclose it. The temporal and fronto-parietal opercula appear first; the frontal and orbital do not develop until a much later period.

"4. The so-called three limbs of the fissure of Sylvius are formed by the meeting over the Sylvian area of the contiguous lips of the four opercula; the posterior horizontal limb intervenes between the frontal-parietal and the temporal operenla; the anterior ascending limb between the frontal and fronto-parietal operenla; the anterior horizontal limb between the frontal and the orbital operenla.

"5. The frontal operculum is therefore the same as the 'cap de Broca,' and it shows great variations in its length. It may be absent altogether, and then the two anterior limbs of the Sylvian fissure are fused into one. When the frontal operculum is reduced in length we have the Y-condition of the two anterior Sylvian rami.

"6. The Sylvian fossa once mapped out on the surface of the hemisphere, it extends very rapidly. The growth is not proportionate with that of the hemisphere, it is much more rapid.

"7. During intra-uterine life the anterior end of the insula maintains a very nearly fixed position with reference to the anterior end of the cerebrum, while the posterior end of the cerebrum moves rapidly toward the occipital pole. After birth the posterior end of the insula is fixed, while the anterior end, as growth advances, oscillates slightly—at first approaching and then retreating from the anterior end of the cerebrum.

"8. An anterior limb of the Sylvian fissures can only be determined by the following tests: (*a*) It must cut right through the entire thickness of the operculum and reach the furrow surrounding the island of Reil. (*b*) It must lie in front of the præcentral sulcus.

"9. A single anterior limb of the Sylvian was present in 30 per cent. of the hemispheres examined; the two anterior limbs, quite distinct and separate, were present in 37.5 per cent.; the Y-shaped condition of the two limbs was present in 31.5 per cent.

"10. The two orbital limbs of the Sylvian fissure cannot be regarded as belonging to the same category of the true anterior limbs. They are not developed as primitive deficiencies in the orbital operculum.

"11. The posterior insula is not connected with the extremity of the temporal lobe, as Erbstaller has asserted, but with the limbic lobe.

"12. On the surface of the fœtal insula there appear three radial furrows which correspond in every respect with the three "Primärfurchen" on the outer surface of the mantle (viz., the fissure of Rolando, the inferior præcentral sulcus, and the vertical limb of the intra-parietal sulcus). The radial furrows on the insula clearly belong to the same fissural system and intermediate links between the three radial fissures on the outer surface of the hemisphere, and the three radial fissures on the insula may exist in the form of secondary sulci, cutting the margin of the fronto-parietal operculum.

"13. The fissure of Rolando is clearly the proper boundary of the frontal lobe. Above, it is only separated from the calloso-marginal fissure, which bounds the lobe internally, by a narrow but superficial gyrus; below, the inferior transverse furrow of Erbstaller acts as an intermediate link between it and the sulcus centralis insulæ. The sulcus centralis insulæ and the calloso-marginal sulcus are brought into close relationship at the anterior perforated spot on the base of the brain. An almost continuous fissural system, therefore, marks out the limits of the frontal portion of the cerebrum.

"14. The temporal pole is formed entirely by the forward growth of the fore part of the temporal operculum.

"15. In the adult brain the insula is proportionately longer in the male than in the female. At all periods of growth it would seem that the insula is relatively longer on the left side than on the right side. In the negro

brain it would appear that the insula is relatively shorter than in the European brain.

"16. In the anthropoid ape the so-called anterior limb of the Sylvian fissure is not homologous with either of the anterior limbs in man.

"17. In the chimpanzee and orang there are only two opercula, viz., the fronto-parietal and the temporal. The frontal and orbital opercula of the human brain are entirely absent in the anthropoid cerebrum.

"18. Restricting the term insula to that part of the hemisphere surface which is concealed from view by opercula, the extent of this area in the ape is very much less than in man. The central index is 18.2 in the chimpanzee and 21.5 in the orang; in man the central index is 29.6. In the lower apes the central index is higher than in the anthropoids.

"19. In man the field of the insula shows marked changes with reference to the cranial wall during intra-uterine life. More and more of its area comes to lie under cover of the parietal bone, and relatively less under cover of the frontal bone, as development proceeds. In the adult the coronal line cuts the insula in such a manner that thirteen per cent. of its length lies in front of it, and eighty-seven per cent. behind it.

"20. In the chimpanzee and the low apes no part of the insula lies in front of the coronal line; in the orang the upper and anterior corner of the insula projects slightly in front of this line.

"21. In the human infant and young child, as well as in the ape, the point at which the stem of the Sylvian fissure reaches the outer surface of the hemisphere is situated relatively further back than in the human adult.

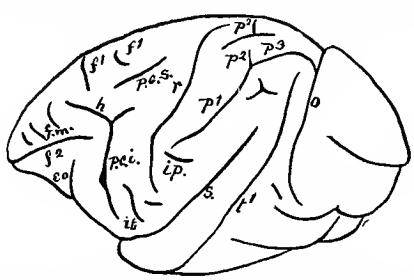

FIG. 475.—Left Cerebral Hemisphere of a Chacma Baboon. *p*, Various parts of the intra-parietal system of furrows; p^1, sulcus post-centralis inferior; p^2, two parts of the sulcus post-centralis superior; p^3, ramus horizontalis; *i.p.*, sulcus post-centralis transversus; *o*, occipital operculum.

"22. The Sylvian fissure is relatively longer in the left hemisphere than in the right, and in the ape than in man. . . .

"28. In the cebus the Sylvian fissure lies above the level of the squamous suture; in the macaque, homadryas, and orang, it lies immediately subjacent to the fore-part of the suture: in *Cynocephalus anubis* and the chimpanzee the fissure is situated in its fore-part below the level of the front part of the suture.

"29. The relative depth of the parietal and temporal lobes in the lower apes resembles that in the human child; in the anthropoid ape the relative parietal depth of the hemisphere exceeds that in the human adult."

The Fissure of Rolando.—Cunningham found that in sixty per cent. of the brains examined the upper end of the fissure of Rolando turned over the mesal border of the hemisphere; in nineteen per cent. its ventral end was connected by a shallow transverse sulcus with the Sylvian fissure. The fissure of Rolando appears in two parts, the lower two-thirds appears before, and independent of, the upper third. The relative position of the fissure of Rolando is remarkably constant. The upper fronto-Rolandic index is 53.3, the lower 43.3. In anthropoid the upper end of the fissure of Rolando is placed relatively further back than in man. The average Rolandic angle in the human brain is 71.7. The average relative length of the fissure of Rolando is 39.3.

The Intra-parietal Sulcus.—"1. The entire sulcus, single and continuous in some of the lower apes (*e.g.*, Cebus), becomes broken up in the human brain into a group of furrows which present different relations to each other in different cases.

"2. Three of the elements of the sulcus in the human brain, viz., the sulcus post-centralis inferior, the ramus horizontalis, and the ramus occipitalis, are disrupted portions of the original fissure; one, the sulcus post-centralis superior, is a superadded element. (Fig. 482.)

"3. In the development of the sulcus in the human fœtal brain, all the four segments of the sulcus have, as a rule, an independent origin, although, as Pausch has shown, the sulcus post-centralis inferior and the sulcus horizontalis very frequently appear as one continuous furrow.

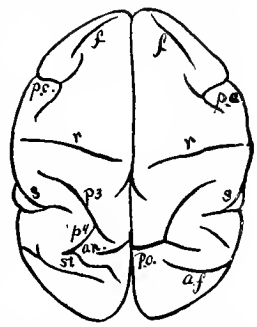

FIG. 476.—Cerebrum of Cebus Albifrons. *f*, Sulcus frontalis inferior; *p.c.*, sulcus post-centralis inferior; *r*, fissure of Rolando; *s*, Sylvian fissure; *p*, intra-parietal sulcus; p^3, ramus horizontalis; p^4, ramus occipitalis; *st*, furrow corresponding to sulcus transversus occipitalis of Ecker; *p.o.*, parieto-occipital fissure; *an.*, first annectant gyrus; *a.f.*, ape cleft.

"4. The sulcus post-centralis inferior usually appears first; then the ramus horizontalis and ramus occipitalis; and last of all the sulcus post-centralis superior.

"5. In Cebus there is no sulcus post-centralis superior, it is present, however, in most of the old world apes, *e. g.*, the baboon, macaque, gibbon, chimpanzee, orang, and gorilla. (Fig. 476.)

"6. In the chimpanzee and orang there is reason to believe that this segment of the post-central sulcus consists of two elements, one placed above the other. (Figs. 479 and 480.)

"7. Eberstaller's third and lower segment of the post-central sulcus (viz., the sulcus post-centralis transversus) is not only present in man, but also in the majority of the old-world apes.

"8. In the apes the intra-parietal sulcus is deeper than the fissure of Rolando, the opposite is the case in man. This would seem to indicate that the morphological value of the sulci is different in man and the apes. The phylogeny and ontogeny of these furrows are in apparent variance with each other. The fissure of Rolando appears first on the developing cerebrum of the human fœtus, yet it is the intra-parietal sulcus which first makes its appearance in the evolution of the primate cerebrum. . . .

"11. In man there appears to be a general tendency toward a union of the two originally distinct post-central elements of the sulcus, and a divorce from the lower of those of the ramus horizontalis. . . .

"13. The ramus occipitalis was connected with the ramus horizontalis in 63.7 per cent. of the adult human hemispheres examined.

"14. The union between these two elements of the sulcus, as Ecker and Wilder have shown, is much more common on the left side than on the right.

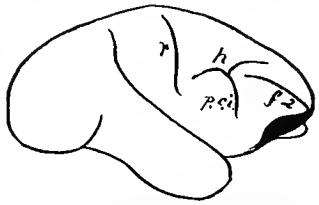

FIG. 477.—The Outer Surface of the Cerebrum of Cebus Albifrons. *r*, Fissure of Rolando; *p.c.i.*, sulcus præcentralis inferior; *h*, ramus horizontalis; f^2, inferior frontal sulcus.

"The sulcus transversus of Ecker is not the homologue of the Affenspalter in the apes, but merely a terminal bifurcation of the ramus occipitalis."

The Sulcus Præcentralis.—"1. The sulcus præcentralis inferior in the human brain is composed of a vertical and

a horizontal limb. The latter is carried forward into the middle of the frontal convolution.

"2. This furrow is the earliest to appear on the outer surface of the frontal lobe of the fœtal brain. In some cases it is seen in the fifth-month cerebrum in the form of a long, deep, vertical sulcus, which subsequently undergoes a retrograde development before its adult condition is reached. In many cases, in its early condition, it presents a form in every respect comparable with that observed in the cerebrum of the low ape (Cebus). Frequently it is developed in several pieces.

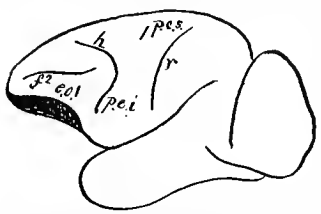

FIG. 478.—Another view of the same: *p.c.s.*, Sulcus præcentralis inferior (?); *e.o.*, a slight trace of the sulcus fronto-orbitalis. Other letters as in Fig. 477.

"3. The sulcus præcentralis superior is closely connected with the basal part of the first frontal furrow. It is usually developed along with it. It consists of two pieces—an upper and a lower—which may be partially or completely separated from each other, as well as from the basal part of the first frontal furrow by an annectant gyrus.

"4. Two additional furrows belonging to the præcentral system are occasionally present, viz., the sulcus præcentralis medius and the sulcus præcentralis marginalis.

"5. The sulcus præcentralis medius may arise in two different ways: (*a*) It may be formed by the ramus horizontalis of the inferior præcentral sulcus divorced from the vertical stem and assuming a very oblique or an almost vertical position; (*b*) it may consist of a new element placed between the superior and inferior præcentral furrows, but showing a closer connection with the former. . . .

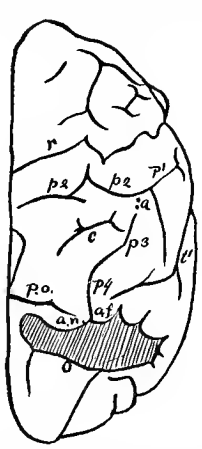

FIG. 479.—Cerebral Hemisphere of Young Female Chimpanzee, as seen from above. The operculum on each side has been removed. *r*, Fissure of Rolando; p^1, sulcus post-centralis inferior; p^2, two portions of sulcus post-centralis superior; p^3, ramus horizontalis; p^4, ramus occipitalis; *b*, terminal bifurcation of the intra-parietal sulcus: *p.o.*, parieto-occipital fissure; *a.n.*, first parieto-occipital annectant gyrus; *a*, deep annectant gyrus in the course of the intra-parietal sulcus; *c*, secondary sulcus in the superior parietal lobule; *a.f.*, bottom of the "ape-cleft;" *o*, cut surface of occipital operculum; t^1, parallel sulcus.

"12. The superior frontal gyrus and the middle frontal gyrus are each partially subdivided into two tiers or subdivisions by furrows which may be respectively termed the sulcus frontalis mesialis and the sulcus frontalis medius.

"13. Both of these furrows have secured a firm footing in the human brain, but only one (viz., the frontalis medius) has established itself upon the brain of the chimpanzee." . . .

"17. The sulcus frontalis mesialis is absent or poorly developed in the brain of the negro. . . .

"20. The sulcus præcentralis inferior and the inferior frontal sulcus are the furrows which are most firmly impressed upon the brain of the apes. In Cebus they alone are present; in Calithrix there are also traces of the sulcus præcentralis superior and sulcus fronto-orbitalis; in the baboon there are, in addition, a rudimentary sulcus frontalis superior, and perhaps (?) traces of a sulcus frontalis medius. (Figs. 475 and 476.)

"21. In the chimpanzee and the gorilla the sulcus frontalis medius is often present in a form precisely similar to that seen in the human brain; in the orang the condition of this sulcus is doubtful; in the gibbon the sulcus frontalis medius is absent.

"22. In the chimpanzee, therefore, the same convolution tiers may be seen as in man, with this exception: the superior frontalis is never split into two by a sulcus frontalis mesialis.

"23. The inferior frontal convolution of apes is very different from that in man.

"24. The frontal and orbital Sylvian opercula are completely absent in the apes.

"25. Consequently, a portion of the island of Reil is uncovered and exposed on the surface of the cerebrum.

"26. The sulcus fronto-orbitalis of apes corresponds to the anterior limiting sulcus of the island of Reil in man.

"27. There are no anterior limbs of the Sylvian fissure in the anthropoid apes. The so-called anterior limb of the Sylvian fissure corresponds to the anterior free border of the fronto-parietal operculum.

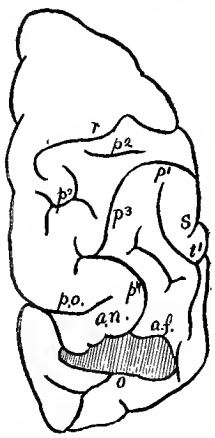

FIG. 480.—Right Hemisphere of a Male Orang, Six Years Old. *r*, Fissure of Rolando; p^1, sulcus post-centralis inferior; p^2, two parts of sulcus post-centralis superior; p^3, ramus horizontalis; p^4, ramus occipitalis; *a.n.*, first parieto-occipital annectant gyrus; *p.o.*, parieto-occipital fissure; *a.f.*, bottom of "ape-cleft;" *o*, cut surface of occipital operculum; *s*, fissure of Sylvius; t^1, parallel sulcus.

"28. About the seventh month of fœtal life the inferior præcentral sulcus of the human brain attains a position which it retains unaltered throughout all the subsequent changes of growth; previous to this it is placed relatively further back on the surface of the hemisphere.

"29. At first it is placed in front of the coronal suture. The sutural line, however, moves forward so that the sulcus ultimately comes to lie behind it.

"30. In the ape cerebrum the inferior præcentral sulcus lies relatively much further forward than in the cerebrum of man. It may be placed subjacent to, or in front of, the coronal line."

Morphology of the Primitive Brain Tube.—Embryology and comparative anatomy are continually throwing new light on the problem of the archetypal structure of the neuraxis.

The most obscure point and one of fundamental im-

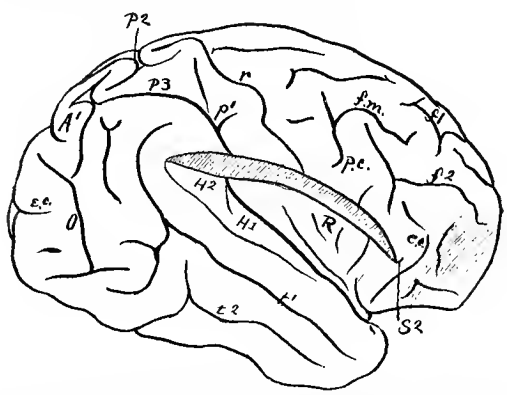

FIG. 481.—Right Cerebral Hemisphere of a Male Orang-outang, Six Years Old. f^1, Sulcus frontalis superior; f^2, sulcus frontalis inferior; *f.m.*, sulcus frontalis medius; *e.o.*, sulcus fronto-orbitalis; *p.c.*, sulcus præcentralis inferior; *p.c.s.*, sulcus præcentralis superior; *p.c.i.*, sulcus præcentralis inferior; *r*, fissure of Rolando; p^1, sulcus post-centralis inferior; p^2, sulcus post-centralis superior; p^3, sulcus horizontalis intra-parietalis; *e.c.*, external calcarine fissure; t^1, parallel sulcus; t^2, second temporal sulcus; H^1, H^2, H^3, transverse temporal gyri of Heschl; *R*, insula; A^1, first annectant gyrus; S^2, anterior free border of the fronto-parietal operculum; *O*, anterior edge of the occipital operculum.

portance in the morphogenesis of the brain is the primitive cephalic end of the neuraxis. The two prevailing schools are represented by Professor His and Professor Kupffer, respectively. It is quite possible that many of the contradictions grow out of the fact that the various authors have been employing different axes.

Professor His uses an imaginary line lying in the base of the tube, and finds that its cephalic extremity coin-

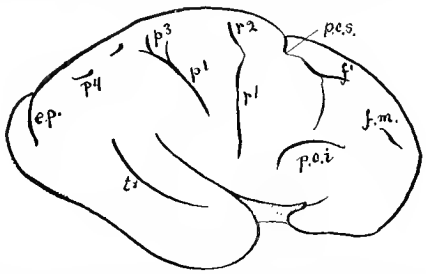

FIG. 482.—Outer Surface of a Cerebral Hemisphere in the Early Part of the Seventh Month: t^1, Parallel sulcus; *p.c.i.*, inferior frontal; f^1, sulcus frontalis primus; *p.c.s.*, sulcus præcentralis superior; *r*, fissure of Rolando; *p*, intra parietal sulcus; p^1, sulcus post-centralis inferior; p^3, ramus horizontalis of the intra-parietal sulcus; p^4, ramus occipitalis; *e.p.*, fissura perpendicularis externa.

cides with the basilary ridge immediately above the recess of Sessel. Others employ a median axis which would terminate in front of the chiasm (Kiebel). Others seem to employ a dorsal axis which, according to His, would terminate in the upper extremity of the terma. To us it seems that the first of these is the most satisfactory reference line, since the diameter of the tube varies greatly, and the length from the termination of the ventral to that of the dorsal axis is by no means constant, while the point of the infundibulum is relatively constant. This selection has another advantage in mak-

ing the chorda coextensive with the neural axis, and obviating the necessity for a distinction between chordal and prechordal brain segments.

When the medullary tube closes it has three lines of union or sutures; the ventral suture marks the line where the chorda was separated, the dorsal suture is the line where the medullary tube has separated from the ectoderm, the frontal suture is the line where the front of the tube closes, though it often remains open for a time, forming the neuropore. At the point where the frontal suture unites with the ventral is a transverse ridge—the basilary ridge—which marks the front of the brain base. Professor His distinguishes a basal plate and lateral alæ, the former giving rise to the motor centres, including the bridge, peduncles, pars subthalamica, and at the cephalic extremity it gives rise to the optic vesicles.

The tendency of the brain to fold sharply in the mesencephalic region is common to all vertebrates. This fold, which gives rise to the saddle cleft, thrusts a part of the base into the cavity of the mesencephalon, producing the tegmental tuberosity, behind which is the recess of the isthmus, and in front of which is the mammillary fossa. The former has been identified by Bürckhardt as a constant element, and the latter has been shown by Herrick to be represented by distinct paired vesicles even in fishes.

The recess of Rathke penetrates more or less caudad of the basilary ridge, and the caudal wall of the recessus infundibuli gives rise to the infundibulum and the upper fundament of the hypophysis. The saccus vasculosus lies between the mammillary recess and the infundibulum. The formation of the hypoaria is due, in the opinion of the writer, to a reduction of the mesencephalic fold. In this case, instead of the formation of the tegmental tuberosity, the excess of the base is thrust cephalolaterad and appears to occupy the walls of the diencephalon.

Respecting the roof of the diencephalon, Professor His[24] has given a summary which is so useful that it is given somewhat at length:

"With regard to the structures called epiphyses, recent times have begun to make sharper distinctions, since Goette has shown that the roof of the diencephalon in amphibia forms two projections, a cephalic ('adergeflechtknoten') and a caudal or true pineal. Since then, the presence of several rudiments has been repeatedly noticed, most recently by Bürckhardt in Protopterus, and Eydeshymer in Amblystoma. The latter author calls only the cephalic projection epiphysis, the caudal paraphysis, and very justly lays emphasis on the fact that the caudal structure appears later than the other. An examination of the profiles of various embryonic brains shows that epiphyses may arise at more than two places.

"The choroidal node found by Goette at the cephalic margin of the diencephalon in amphibia, belongs to the category of cephalic epiphyses. Here it is easy to distinguish them, as the distance between the two is very great. The epiphysis of Selachii also arises from the cephalic part of the roof of the diencephalon. Later, however, almost the whole diencephalic roof is elevated, and there results the familiar projection included between fore-brain and mid-brain, and whose base extends caudad nearly to the post-commissure. Similar conditions prevail in teleosts. An epiphysis of the cephalic roof of the diencephalon was encountered by me in a human embryo 10.5 mm. in length.

"The roof-plate forms at this stage a small median longitudinal ridge with two lateral angles. Cephalad this ridge is triangular, and the median angle separates for a short distance as an independent appendage.

"When I first discovered this structure, some years since, I fancied I had solved the history of the pineal, and only a careful profile reconstruction revealed the fact that this body belongs to the very front of the roof of the diencephalon. The body seems later to disappear in the folds of the plexus.

"The true epiphysis develops much later, after the post-commissure is already formed, by protrusion of the most caudal part of the diencephalic roof. In the bird brain, as even Remak noticed, the epiphysis arises from the middle of the diencephalic roof, and the same is true for the epiphysis of reptiles.

"Thus we distinguish epiphyses of the front, middle, and posterior of the diencephalon roof. For the latter name pineal may be usefully retained.

"Besides these special forms of outgrowth, we en-

counter an elevation of the whole roof, as in Selachii and Teleostei. Goette's "Adergeflechtknoten" certainly pertains exclusively to the group of anterior projections, while the so-called parietal eye of reptiles belong to the middle group." [Later investigations proved it to belong to the posterior group.]

Bürckhardt gives the following arrangement of the parts of the diencephalic roof: 1, Præplexus; 2, velum; 3, "Zirbelpolster" (paraphysis); 4, supra-commissura; 5, pineal; 6, intercalary segment; 7, post-commissura. This seems to be a satisfactory arrangement, except that it fails to take into account the development of the projections from the region of the præplexus which are mentioned by His. There is a remarkable constancy in arrangement of these parts. The writer has shown that the current opinion that the pineal is absent in reptiles rests on a mistake. In serpents the pineal is greatly modified, being a very large lymphoidal body occupying a sling of membrane above the supra-commissure, and is connected either with it or the "Polster," or roof in front of the commissure. The structure of the body is very like that of the glandular part of the pituitary. In turtles there is a large and well-developed tubular pineal as well as a strong flexiform outgrowth cephalad. It is easy to discover that the tube is connected directly with the third ventricle just caudad of the supra-commissure. In ganoid fishes the tubular pineal is well developed and is closely associated with the dorsal sac or expanded roof of the thalamus and aula. There is an enormous plexiform development of the pallium taking the place of the præplexus. In all essentials teleosts agree with the ganoids.

Among the most remarkable structures are the hypoaria of fishes (Fig. 484) which are not externally obvious in other groups.

The hypoaria have usually been considered appendages of the thalamus, but Herrick insists that they are morphologically caudad of the mammillaria, and contain elements of the pes pedunculi or the cephalic part of the floor of the mesencephalon. In this connection he identifies the peculiar cells with which the motor peduncles unite with similar cells in the reptilian mesencephalon and that of mammals. The corpus rotundus is identified with the nidulus ruber, and the latter is shown to be the centre of sensory redistribution, as the before-mentioned cells are of motor connection (especially with the cerebellum).

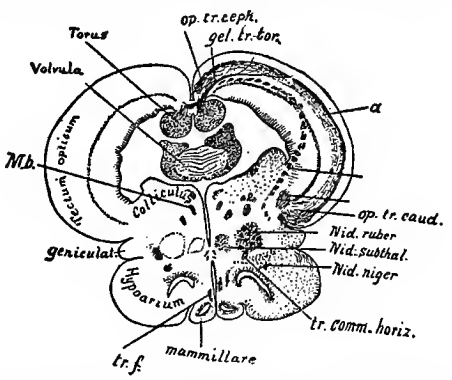

FIG. 484.—Transection of the Brain of a Small Bass. Diagrammatic. Especially designed to show the position of the mammillaria and fornix tract (*tr. f.*) as well as the general relations; *gel. tr. tor.*, gelatinous tract from the torus to periphery of the tectum.

The great consolidation in this region in mammals, and higher vertebrates generally, is largely effected by what Professor His terms the saddle cleft, *i.e.*, the fold of the floor of the mesencephalon, which fills the cavity of the mesencephalon. In embryonic reptilia the mesencephalon is obviously double, and this seems to be universally true at some stage. The cephalic diverticle is pushed cephalad and participates in the curvature of the first embryonic vesicle, while the second is lost in formation of the saddle cleft. The isthmus, or cephalic neuromere of the medulla, is obscured by the development of cerebellum and pons and has no corresponding nerve-roots. The trigeminus springs from two neuromeres, the facial and auditory from a single neuromere, as does the glosso-pharyngeal. It is not yet clear what relation is sustained by the tenth and twelfth nerves to the neuromeres from which they spring. The relation of the chorda to the neural tube, from a morphological point of view, is greatly illuminated by the discovery of Selenka,[25]

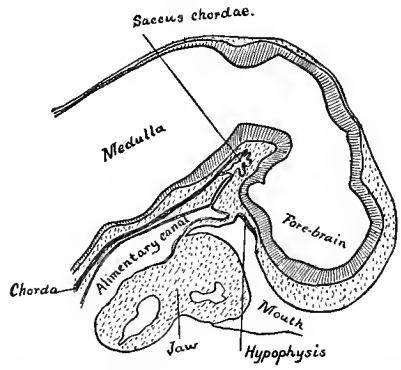

FIG. 485.—Illustration showing the Relation between Chordal Sac, Alimentary Canal, and Brain Flexure in Opossum. (From Selenka.)

that in the opossum there is a curious tortuous tube, apparently related to the cephalic end of the entoderm, but which is really a hollowed and contorted modification of the chorda. Selenka reminds us of the origin of the chorda as an originally hollow diverticle from the entoderm.

The contorted modification must be ascribed to the head-fold which interferes with the normal forward growth of this body, and coils it within the space behind the infundibulum.

This tubular body is quite distinct from the hypophysis, which develops as usual from the ectoderm. This fact, taken in connection with Professor His's statement that the neuropore is coextensive with the whole area from infundibulum to terma, strongly enforces the view that the infundibulum (or at least the basilary ridge) is at the morphological front of the neuraxis.

NERVOUS SYSTEM: HISTOGENESIS OF ITS ELEMENTS. To Professor William His, Sr., of Leipzig, science is chiefly indebted for the generalizations formulating the laws of development of the nervous elements.

Three sources may be recognized for the various elements included in the central nervous system. First, the materials directly or indirectly derived from the primitive epithelium of the neural plate and tube; second, cellular or other products (exudates) from the circulatory vessels; third, migrant (connective) cells and cell-products from the adjacent tissues. Inasmuch as the first class is, strictly speaking, the primitive and essential group, we restrict our notice to it. Even in the medullary plate the columnar epithelium suffers modifications, but these modifications are precisely like those changes which may be observed in sensory epithelium generally. The nuclei, which originally nearly filled the cell, are left near the centre, while an outer and ental space is developed by the growth of the cell (Fig. 486). The ectal portion undergoes a rapid change. A fluid substance accumulates in the granular protoplasm, at first in the form of small vesicles, which subsequently fuse with each other and leave only an irregular reticulum of the more indurated substance. (Fig. 487).

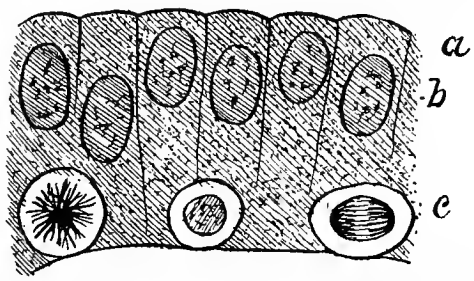

FIG. 486 (After His).—Neuro-epithelium with Ectal Zone (*a*); Ental Zone (*c*), containing neuroblasts with karyokinctic figures; and a Median Zone (*b*) containing the nuclei.

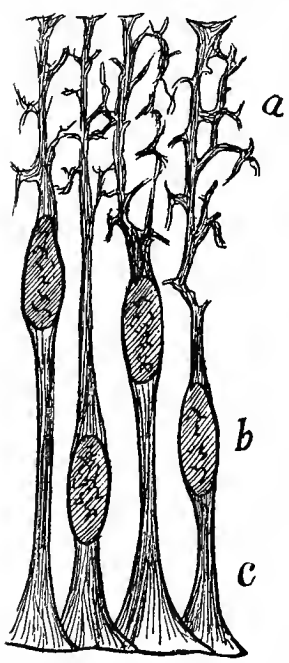

FIG. 487 (After His). — A Later Stage. The ectal layer has been reduced to a reticulum, while the ental portion acquires columnar structure and the nuclei are scattered at various positions in the columnar portion.

The process just described results in the production of a *neurospongium, i.e.*, a sort of framework, in the interstices of which the genuine nervous elements are formed. The primitive cells which are thus modified are spongioblasts, and are the non-nervous elements in the neuro-epithelium. The spongioblast, then, consists of an inner columnar portion, a middle nucleated zone, and a peripheral marginal or "veil" portion. The columnar inner portion never loses its individuality, and forms the so-called lining epithelium of the ventricles and other cavities of the central nervous system.

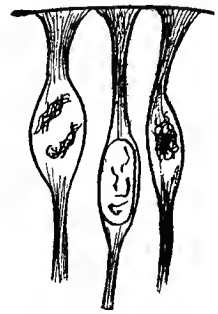

FIG. 488 (After His). — Spongioblasts, with Mitosis of Nuclei.

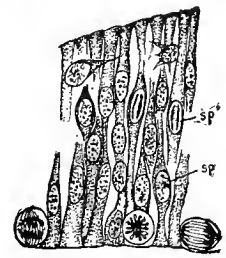

FIG. 489 (From Herrick). — Part of the Mesencephalon of a Garter-snake Embryo, showing numerous neuroblasts, with karyokinetic figures and two spongioblasts (*sp'*) in the same process.

In reality this endyma is not a true epithelium, but is composed of the persisting bases of cells which, morphologically, and generally structurally, retain a connection with the ectal part of the brain-tube. The so-called connective or supporting elements of the retina, organ of Corti, and even of the olfactory epithelium, have essentially similar structure. The spongioblasts multiply to supply the exigencies of the growth of the organ, and mitosis may occasionally be detected in the nuclei. (Figs. 488 and 489.)

Professor His considers that the spaces in the marginal portion of the neurospongium are all produced from vacuoles in the cells, *i.e.*, are intra-cellular. The present writer is convinced that in lower vertebrates, at least, these spaces are intercellular, and the peripheral portion of the cells simply collapses, leaving the interspaces to be filled by an exudate soft and nutritive enough to facilitate the growth of the neurons. (Figs. 489, 490, 491.)

That the entire thickness of the brain-walls is penetrated by the thread-like rudiments of the spongioblasts is well proven.

The Neuroblasts.—It remains an open question whether the rudiments out of which the nervous elements are formed are from the first distinct, or whether the former may be continuously produced up to a certain period by the subdivision of an indifferent epithelium. In any event, at a very early stage there are scattered among the bases of the spongioblasts ovoid or spherical cells, with large dark nuclei, which are in all stages of cell-division. After subdivision these neuroblasts withdraw from the ventricle, adjacent to which they are always formed, and either assemble in various portions of the marginal zone to undergo immediate transformation into

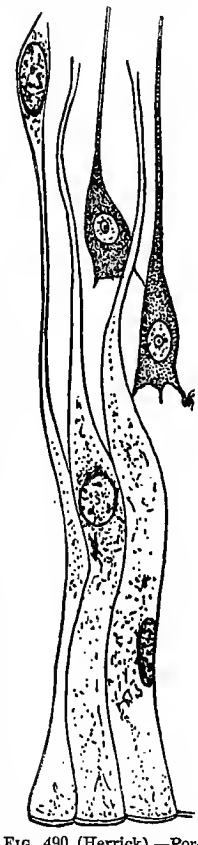

FIG. 490 (Herrick).—Portion of the Tectum (of the optic lobe) in the Trout, showing the neuroblasts in the interspaces between the spongioblasts.

functional neurons, or accumulate in the nucleary zone in the form of reserves. It seems proper to conclude that all the genuine nerve-cells and fibres in the central system are thus formed from epithelial proliferation or indirect derivation from the same source. In those regions of the tube in which neurons are not formed (as over the roof of the fourth ventricle) the resulting structure is a plexus-former, velum, or some other secondary structure. The rate at which neuroblasts are formed varies greatly in different parts of the brain and in different animals. In fishes, the whole cortex (pallium) fails to develop neuroblasts, and it, therefore, has the character of a velum. In human embryos the formation of neuroblasts ceases at the end of the second month, at least in the medulla, and the period of greatest activity is during the development of the nerve-roots. After the birth of the neuroblasts they migrate peripherad and seek their definitive positions. Professor His claims that the neuroblasts of the dorsal part of the tube behave differently from those of the ventral part. The former emerge from their original sites obliquely, so that they turn parallel to the surface and send their processes ventrad and even to the median line. The ventral neuroblasts strike the surface perpendicularly, and the axis-cylinder given off passes out to become a motor nerve.

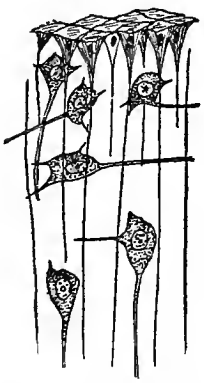

Fig. 491 (Herrick). — A Portion of the Dorsal Ventricular Surface of the Axial Cerebral Lobe of Amiurus, showing the connection of the epithelium cells with the fibrous framework, and also the oblique position of the ventricular cells, while the deeper cells connect directly with the axis-cylinders of the peduncles.

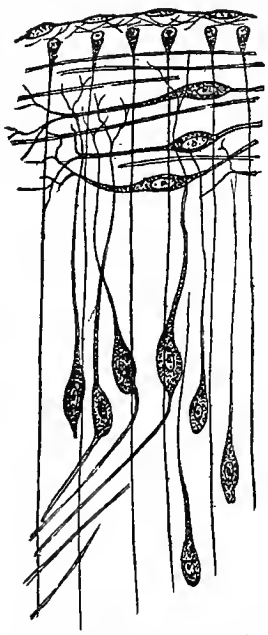

Fig. 492 (Herrick). — A Portion of a Longitudinal Section of the Tectum of Trutta Fario, Nine Days Old, showing the horizontally placed optic tract cells and the connection of the inner cell layer with the lemniscus fibres. The spongioblasts are reduced to mere fibres, terminating in small knobs ectad. [These figures are from the *Anatomischer Anzeiger*, vii., 13 to 14.]

Such migrations are especially remarkable in the medulla. Although similar to the spinal cord at first, it soon becomes divided on either side by a longitudinal fissure into an axial portion and lateral alæ. The motor niduli of the hypoglossus, accessory, vagus, and glosso-pharyngeal are accumulated from the neuroblasts formed in the axial part. The tractus solitarius is formed out of fibres from the glosso-pharyngeus and vagus, and lies along the boundary between the axial and ala portion.

According to Professor His, the alæ fold upon themselves, and from the neuroblasts formed out of these pockets spring the olives, accessory olives, and other clusters of cells isolated from their fellows.

In the case of the cerebellum there is some evidence of a more or less extensive dorsad and cephalad folding of the lateral walls, by means of which the proliferating epithelium is brought into immediate relations with the parts to be supplied. The cells of Purkinje, as well as those of the dentate nidulus, are derived from proliferating epithelium of the ventricles. Throughout the higher regions of the brain there are entirely analogous processes. The striata are centres of rapid proliferation. There are formed great masses of cells, some of which seem to suffer suspension of development until demands are made. The exact nature of the intermediate stages, and the factors which determine the length of time during which proliferation may continue, are obscure. The "granules," such as are so abundant in the cerebellum and olfactory tuber, are undoubtedly mostly developed from the same process of epithelial proliferation.

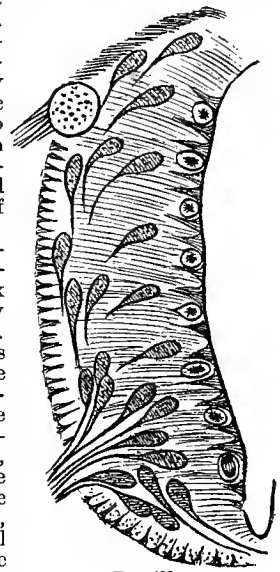

Fig. 493.

The processes just described are somewhat modified in the cerebral cortex (Figs. 494 and 495). They are similar in all animals. The rapidly dividing cells accumulate to form a dense zone near the ventricle, leaving only the marginal zone free. Into this the neuroblasts begin to pass, and, from being radial, become parallel to the surface. The axis-cylinder grows rapidly, while, from the opposite end of the cell, the protoplasmic processes emerge and ramify intimately in the mass. A comparison of Figs. 494 and 495 shows that in the embryo snake and the embryo dog similar conditions prevail.

The early proeesses are comparatively well understood, but toward the close of the embryonic development a phenomenon is encountered, which is variously interpreted. The ectal portion of the massive organs, especially the cerebrum and cerebellum, become somewhat rapidly clothed with a dense mass of granules which subsequently disappear (Fig. 496). Professor His suggests that these are white blood-corpuscles which, after wandering from the sinuses surrounding the organ, make

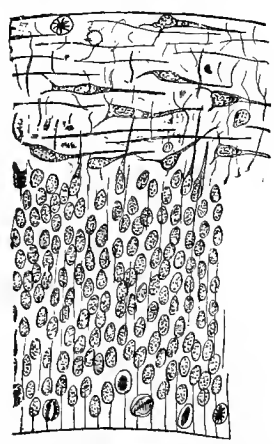

Fig. 494 (Herrick).—Portion of the Base of the Thalamus Vesicle in Young Snake Embryo. *K*, karyokinetic figures in the young neuroblasts near the ventricle. The spongioblasts (*op*) are elongating; *gr*, granules formed from the neuroblasts; *nb*, neuroblasts transforming into neurons, of which the axis cylinder (*a.c.*) processes are directed parallel to the surface.

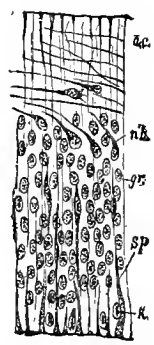

Fig. 495 (Herrick). — Similar Section from Dog Embryo. The section is from the frontal region of the right hemisphere. The relations are as described under Fig. 494, except that the neurons have begun to develop protoplasmic processes as well as the axis-cylinder.

a temporary halt near the surface before passing throughout the substance of both gray and white matter. The period at which they appear in the human embryo is about the end of the second month. While not doubting the existence of amœboid cells as above described, the writer has suggested other sources for part of these cells. It will be noted that the peripheral zone of cells arises only after direct communication with the ventricles has been cut off by interpolated white matter. Subsequently the number of granules (*e.g.*, beneath the Purkinje layer in the cerebellum) rapidly increases. Their source can only be the peripheral collection of granules. Fig. 496 shows that, at this stage, there is often rapid multiplication going on within that layer. Careful study has not revealed any other source for these proliferating granules than diverticles of the epithelium, from which migration in this more round-about way is kept up. It is a familiar fact that the earlier granules are derived from the proliferating neuroblasts of the ventricular surface; it is inherently improbable that the subsequent ones should spring from as distinct a source as the pia or its vessels. The peripheral proliferating layer soon disappears by the migration of its elements toward the ventricle.

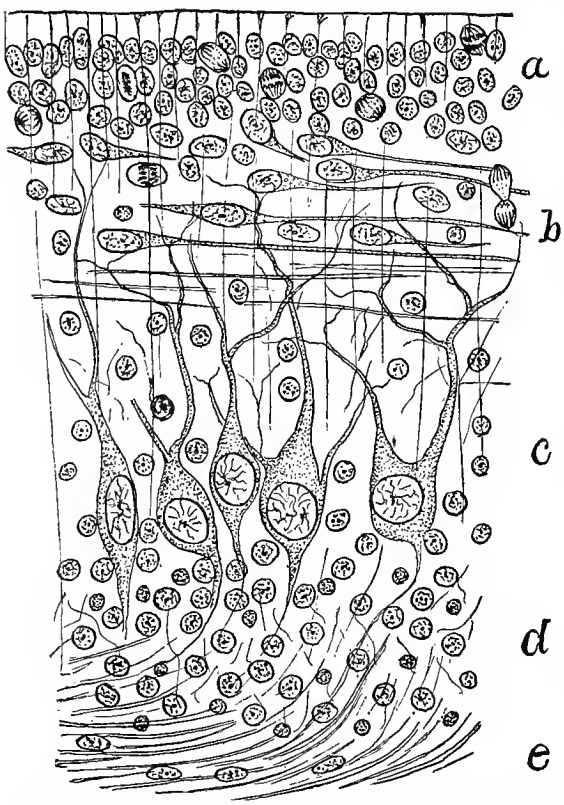

FIG. 496.—A Section of the Cerebellum from Embryonic Opossum. *a*, Superficial proliferating zone; *b*, tracts and cells of the molecular layer; c, Purkinje's cell layer; *d*, granular layer; *e*, fibre zone.

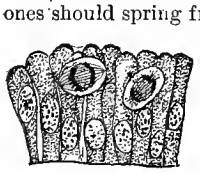

FIG. 497.

There can be no doubt that the study of the conditions determining the proliferation of neuroblasts are of the highest importance in construing the causes of precocity, senility, and decline.

The Organs of Special Sense.—The essential similarity of the sensory and nervous epithelium has already been pointed out, and may be a warrant for deriving the latter from the former phylogenetically. In the case of the retina we have the very remarkable instance of a diverticle of the brain, which is mechanically invaginated, resulting in the conversion of the invaginated portion into a highly modified form of brain tissue (retina), and the uninvaginated portion into a pigmented velum (pigment layer). Accompanying and co-operating with this process is the conversion of a portion of the superficial sensory epithelium, first into a ciliated sac, and then into a solid and transparent mass (the lens and capsule) without the formation of permanent neuroblasts.

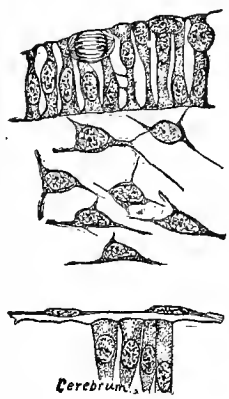

FIG. 498.

Preliminary to the development of the sensory organs, the existence of an undifferentiated sensory epithelium, or *cephalic sensory plate*, must be recognized. This plate, whose morphological cephalic end is at the infundibulum, extends over the convexity of the head and arches laterad, including the prerudiments (anlags) of the lens and arches, caudad to include auditory sac (anlag) and lateral (bronchial) sensory apparatus. The epithelium is essentially uniform over the entire area in an early period (Fig. 497). It consists of columnar epithelium (spongioblast) cells with scattered neuroblasts near the ectal surface.

The subsequent modifications are very like those of other nervous lamina. The neuroblasts migrate toward the ental surface and there accumulate along the distended ental portions of the spongioblasts. The process may be easily traced in the case of the olfactory. It will be recalled that phylogenetically the olfactory is a dorsal organ, and is connected by the pituitary (hypophysis) with the infundibulum or morphological front of the brain. By the development of the projecting walls of the head the olfactory anlag is carried forward, the growth being from the angle of the mouth cephalad, as can be shown by observing the direction of invagination of the olfactory sac. Jacobson's organs are intermediate between the olfactory and the hypophysis. Fig. 498 illustrates the first changes in the future olfactory epithelium. The ental portion of the spongioblasts is becoming disassociated and the formation of a reticulum is begun. In Fig. 499 the migration of the neuroblasts toward the inner surface and the incipient invagination is shown, while Fig. 500 illustrates the origin of the olfactory nerve by migrating neuroblasts. In the way indicated the olfactory nerve impinges upon the cephaloventral or lateral aspects of the hemispheres, and there proliferates and calls out the development of the peculiar structure of the olfactory pero. The subsequent connection of the pero with the hippocampal region by means of the radix lateralis is especially well shown in fishes and in other classes of lower vertebrates. That a portion of the same fibres enter the walls of the thalamus is suggested by a study of mammalian embryos.

FIG. 499.

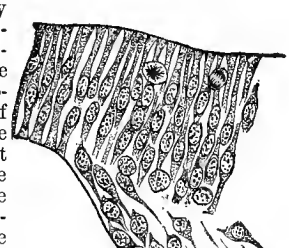

FIG. 500.

The fact that the lens is essentially a sensory depression, homologous with the nasal sac, is one of the well-established generalizations of the last few years. In this

case, however, neuroblasts are not developed, and the spongioblasts undergo very remarkable gelatinous transformation, though the nuclei may always be demonstrated by sufficient preparation.

The internal ear is the next organ of this lateral series, and its formation beautifully illustrates the uniformity in diversity characteristic of all morphological processes. The auditory sense organ, like the preceding, is an invagination of specialized sensory epithelium continuous with that which, in lower vertebrates, forms the "organs of the lateral line." It first appears as a saucer-like depression (Fig. 501), from which is formed the capsule from the various transformations of which the "membranous labyrinth" with its sensory patches is formed.

The primitive sac divides into a cephalic and caudal portions. Comparison of the methods of development of the lateral line-organs in the dogfish, for example (Ayers), shows great similarity with the early morphological changes in the ear by which the semicircular

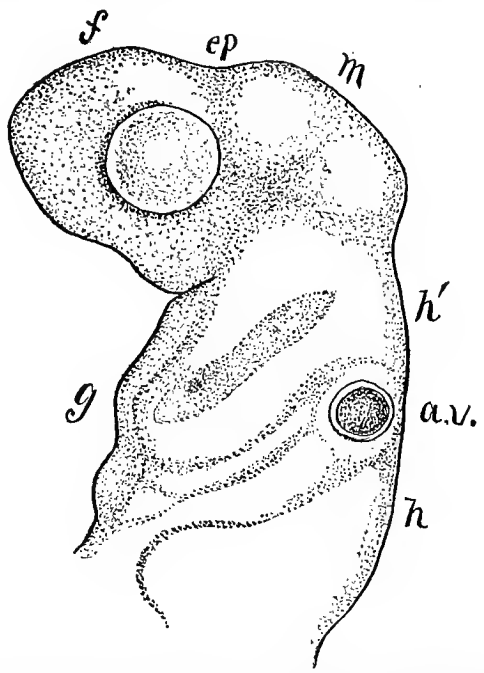

FIG. 501 (After Ayers). — Head of Embryonic Shark, *Acanthias vulgaris*, showing the saucer-like depression, showing the insinking sense-organ which is to be converted into the auditory sense-organs of the shark. *a.v.*, Auditory vesicle; *ep*, position of epiphysis; *m*, mesencephalon; *f*, fore-brain; *g*, gill-region; *h*, medulla.

canals are formed. "Within the two chambers formed four canal sense-organs develop. The two external organs are soon enclosed within the ampulla of the two complete and relatively large canals which are now formed about them." "Up to this time the organs have retained the primitive relations to each other, a serial arrangement along a line running in an antero-posterior direction. Now there begins a distortion of the structure as a whole, which continues ever after and reaches its greatest development in the mammals, viz., a process of sinking and drawing out ventrally of the posterior chamber of the ear, so that hereafter we might speak of a superior and an inferior portion or chamber" (Ayers). By progressive subdivisions the four patches give rise to the eight definitive auditory sensory organs of mammals. Meanwhile, the neuroblasts have migrated to the ectal surface and give rise to the two ganglia (vestibuli and cochleæ) from which the two branches of the auditory nerve are produced.

The transformations of the epithelium in the formation of the organ of Corti are out of place here, but obey laws easily intelligible from our knowledge of the history of the spongioblasts elsewhere.

The retina is essentially a modification of a portion of the primitive neural tube. The pigment layer undergoes a change directly comparable with that which produces the velum cerebelli or the introductory stages of plexus formation. The original limits of the tube are represented in the retina by the membranæ limitantes.

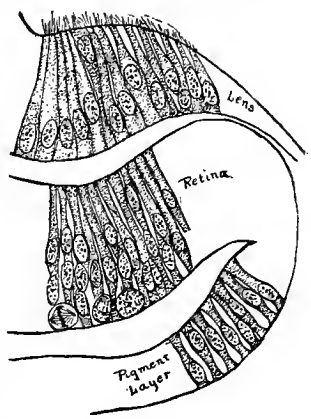

FIG. 502.

The relations are at first exactly as in the brain proper (Figs. 502, 503). The neuroblasts are formed adjacent to the ventricular surface and migrate to the ectal surface. A portion remains in the nucleary (granular) layers and corresponds to the granules which lie adjacent to the ventricles in the brain. The method of formation of the rods and cones is still a matter of dispute. Professor His thinks they are formed by protrusion of backward-growing processes of the neuroblasts. It is, perhaps, doubtful if we have not to do with the nuclei of the spongioblasts and the greatly modified homologues of the cilia characteristic of ventricular epithelium. In any case the true neurons collect in a single or double series on the vitreous surface of the retina, and give rise to an axis-cylinder process which passes through the chiasm to the tectum opticum, and to protoplasmic processes which subdivide in the "inner molecular layer" (equivalent to the marginal reticular zone of the brain). The direct connection between the ganglion cells and the rods and cones has not been observed, and probably the connection is through a reticulum or neuropilem as in all other cases. The nerve-fibres develop in the human retina at about the fifth week. It is obvious, from the results of recent investigation, that fibres arising in the teetum opticum pass toward the retina as well as vice versa.

The spinal ganglia, which originate near the margin where the medullar tube separates from the ectoderm, appear in the form of a band on either side the tube. The aggregation into separate ganglia may be ascribed in part, at least, to the mechanical effect of the myomers or primitive vertebrate. The neuroblasts of the ganglion put forth a process which penetrates the medullary tube and at once divides into an ascending and descending ramus. From these rami short branches are formed which engage processes of the motor cells of the ventral cornua and form reflex channels, while other communicating tracts are related to the columns of the cord. The opposite extremity of the neuroblast passes to the peripheral end organ. During early stages the neuroblasts are motile, and, either as a result of a common impulse or by the results of the growth of the tube, they come to lie upon the lateral aspects of the cord. Connection is effected in a secondary way between the motor and sensory roots, and experiments have even shown that motor fibres may find exit via the sensory ganglion; for many of the purely motor nerves temporary embryonic ganglia have been reported, but it is to be feared that such reports rest on false conceptions of the method of proliferation of the nerve itself. (Figs. 504, 505, 506.)

FIG. 503.

Respecting the development of nerve-fibres, our opinions have been very largely moulded by the great work of Flechsig, who describes, somewhat in detail, the origin

of the sheaths from special amœboid cells. Only quite recently, in the case of the olfactory, it has been shown that the nerve is composed of moniliform series of neu-

Fig. 504. (From His)—Illustrates the origin of the Spinal Ganglia from the Connection between the Neural Tube and the Ectoderm. It is stated by some observers that the ganglion anlags temporarily fuse and again separate.

rons. Kölliker says: "In my studies upon the development of the organs of smell in human embryos I discovered that the olfactory, unlike all other nerves, in the

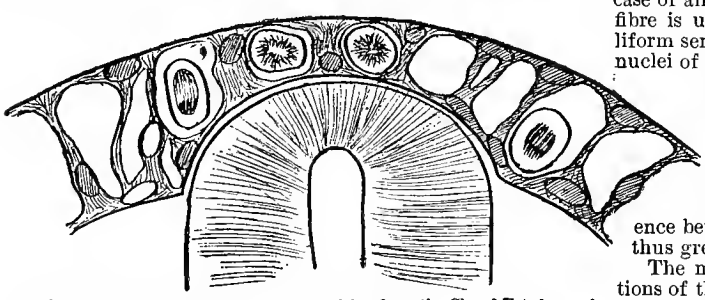

Fig. 505.—Stage in which Neuroblasts are arising from the Closed Ectoderm after Separation of the Neural Tube.

earliest stages consist throughout their entire extent of nucleated bundles of the finest parallel fibrils, which bundles I compared with the axis-cylinders of other nerves. From this circumstance I concluded that these nuclei correspond to the nuclei of nerve-cells, and that a nucleated sheath of Schwann, accordingly, is not present, although it has been assumed by all authors since Max Schultze. If this were correct, then the olfactory fibres consist of bipolar nerve-cells, which either each sends a process peripherad, or, as seemed to me probable, are united in moniliform series, as must be assumed in the sympathetic; in this case the nerve grows by successive subdivision of the nucleated portions without complete separation of the resulting segments.

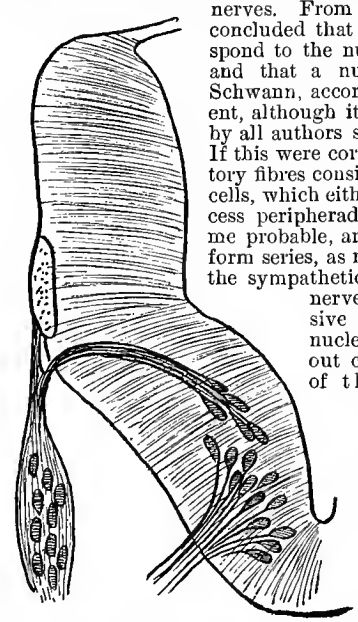

Fig. 506.—Diagram Illustrating the Origin of a Medullary Nerve, with the Sensory Portion derived from the Tractus Solitarius, which is at the demarkation between basal plate and ala.

"In any case the development of such a nerve from the central nervous system is difficult to explain from any existing analogy, and it afforded a very desirable solution of the matter when His, a short time since, announced that the olfactory does not develop from the olfactory lobe, but rather takes its origin from the epithelium of the olfactory pits, and grows in the centripetal direction, like the cells of the spinal ganglion. This investigation of His I have recently verified with the following results:

"In the earliest stages the olfactory pits have no nerves, and are not connected with the olfactory lobe. In an embryo chick of four days there is a slight proliferation of the epithelium of the olfactory at the end nearest the brain only, forming a bundle .030–.054 mm. thick, which can be followed to the outer margin of the hemisphere without entering into any connection therewith. The bundle is finely fibrous and nucleated, and exhibits on its surface fusiform cells."

Professor His regards the nerves themselves as the olfactory ganglion. These cells, inasmuch as they were originally epithelium of the nasal pit, have undergone a considerable migration, so that the question naturally arises whether all the nerve-cells of the olfactory ganglion have not gradually entered the bulbus. Professor Kölliker does not believe that the cells grow into the bulbus, while His supposes that they do thus enter and proliferate.

The present writer is tempted to believe that, in the case of all sensory, if not motor nerves, the definitive fibre is usually the result of the fusion of a moniliform series of neurons whose nuclei remain as the nuclei of the sheath of Schwann. The well-known fact that during degeneration the nuclei of Schwann's sheath begin to proliferate, seems to point in the same direction. Huber has shown that the theory that these nuclei are latent and preformed in the sheath, and the other that the nuclei migrate from node to node, are equally untenable. The difference between the sympathetic and spinal nerves is thus greatly diminished.

The modifications going on in the several portions of the brain itself as it approaches maturity are too numerous to be followed in detail. Among the most important of these are the formation of what may be termed switch stations in the brain. Such stations are the nidulus ruber (sensory) and the cells of the isthmus region (pes pedunculi) where the connections are effected with the cerebellum. These relations are most beautifully shown in reptiles and fishes (Fig. 507).

The structure of the ruber is peculiar in the dense

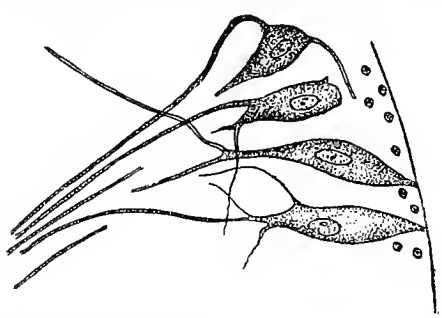

Fig. 507.—Switch-cells from the Hypoaria (Lobi inferiores) of Fishes. These cells connect directly with the motor-tracts from the cerebrum, and indirectly with the cerebellum. (Herrick.)

structure of the neuroglia, the great abundance of blood-vessels, and the tendency, in some groups, to suffusion with proteid matters. In the fishes the body which has been identified with the ruber has a peculiar spotted appearance which has been resolved into dense clusters of cells in a suffused investing stroma, as illustrated by Fig. 509. The olives, whose origin has already been described, are similar to the above-mentioned, both probably being derived from invaginated portions of the original ventricular epithelium.

In conclusion, it must be admitted that the most im-

portant factor in the preparation for a rational interpretation of the perplexities of the nervous mechanism is the

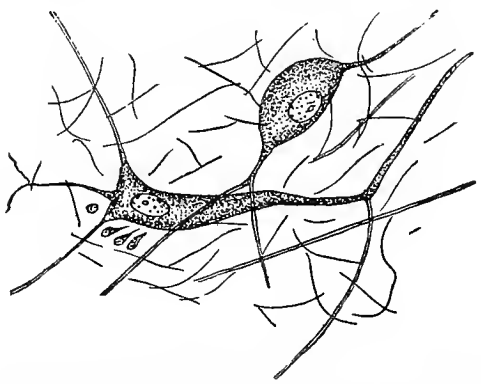

FIG. 508.—Cells from the Peripheral Portion of the Ruber. These cells communicate with the dorsal sensory tracts from the cerebrum. (Herrick.)

recognition of the essential unity of the process of nervous development, and of the existence of a single typical nervous element—the neuron—through the endless com-

binations and modifications of which the entire central system has been produced. *C. L. Herrick.*

NEYRAC. A small watering-place in Ardèche, France.

LOCATION.—Neyrac is prettily situated on the right bank of the river Ardèche, about two miles from Vals. The place has a number of alkaline-calcareous springs. The *Source les Bains* is the only spring now in active use. The temperature of the water is 80° F.

INDICATIONS.—The waters of Neyrac have the reputation of being tonic, slightly aperient, and solvent. They are made use of in certain skin diseases, rheumatism, scrofula, chlorosis, gastralgia, and female disorders. In olden times they enjoyed a great reputation in the treatment of leprosy.

ACCOMMODATION.—There is a small thermal establishment and several clean lodging-houses. Nothing approaching the requirements of modern scientific bath treatment has yet been established at this resort.

Edmund C. Wendt.

NICE. This city, which continues to be the most popular resort on the Riviera, has already been described in its main features in Vol. VIII. of the HANDBOOK, under the article "Riviera." The writer having recently spent a winter there, it may be well to briefly indicate the results of some of his personal observations. For a more detailed account the reader is referred to the writer's report, which was published in the *Medical Record*, March 12, 1892. So far as its claims go to be considered as a first-class health-resort, the town of Nice has received from different authors both exaggerated praise and undue condemnation. There is no doubt that the rapid growth of this city, accompanied by deficient sanitary arrangements, has vitiated the old title of Nice to rank as the best natural winter sanitarium on the north shore of the Mediterranean. But despite its undeniable imperfections, the town still attracts large numbers of invalids and pleasure-seekers, who often loudly complain but yet return to its hospitable shores winter after winter. This, in itself, is an argument in favor of Nice.

In regard to the important matter of drinking-water, it appears that the source mentioned as impure in the writer's report has now been suppressed by the authorities. The water supplied by the Nice Company is carried from distant hills in a completely closed aqueduct. It has the following composition:

ANALYSIS OF THE NICE DRINKING-WATER (made by M. Durand-Clay, de l'École des Ponts et Chaussées):

Ingredients of one litre, evaporated to dryness.	St. Theole.		
	Crevice in rock.	Source of Prê.	Peillon source.
	Gr.	Gr.	Gr.
Insoluble residue	0.010	0.004	Traces
Alumina and peroxide of iron	0.001	0.001	Traces
Chalk	.....	0.085	0.050
Magnesia	0.016	0.009	0.040
Alkalies (various)	0.016	0.008	0.030
Chlorides	0.013	Traces	0.020
Sulphates	0.005	0.011	0.010
Organic matters	0.016	0.003	0.030
Carbonic acid and unclassified substances	0.054	0.059	0.060
Total residue of evaporation of one litre	0.212	0.180	0.240

The water is thus seen to be a mixed one. It is hard, chalky, and very slightly acidulous to the taste. Filtration is not necessary, but boiling would of course destroy the traces of organic admixture that it undeniably contains.

Most of the dangerous old wells of Nice have been closed up, and a foreigner need not fear the Company's water at the present time.

As regards drainage difficulties, some notable improvements are already well under way. The writer's report mentions this subject as follows:

Fully recognizing the shortcomings of their present system of sewage disposal, the authorities are now considering two new plans for perfecting the same. The first of these is M. Bérard's plan. It is quite simple, and would be comparatively inexpensive. After rectifying, repairing, or newly constructing a comprehensive system of street sewers, a large collecting conduit is to be built parallel with the shore line. This will carry the sewage down to the river Magnan by a natural incline. Thence either an iron conduit will convey it nearly five hundred feet out to sea, or it will be used in fertilizing country fields. The advantages of this plan are that it is cheap, feasible, and measurably effective.

The other plan is a more extensive and expensive one, but having been abandoned need not be described. The writer has quite recently learned that several objectionable open sewers and contaminated streams have already been canalized, and that the municipal authorities are evidently hard at work to perfect their drainage system. There is little doubt that the diminished prestige of Nice will in some measure return as soon as the most urgent sanitary reforms shall have been carried out.

In regard to the healthfulness of Nice, it may be said

that the city's death-rate will bear favorable comparison with that of most French towns. Moreover, it appears to be diminishing rather than increasing. In justice to this much-abused city, it should also be borne in mind that, in calculating percentages, the permanent population is used as a basis. The census of 1891 gives Nice 97,720 inhabitants. But as there is a large floating population, estimated to reach 30,000 or 40,000 during the season, and as many invalids go to Nice to die, it follows that the actual death-rate, chargeable to the town proper, must be even lower than the official returns make it. These figures are given by the Board of Health :

In 1883.....	30.75	deaths	per 1,000.
" 1884.....	29.55	"	"
" 1885.....	28.82	"	"
" 1886.....	24.60	"	"
" 1887.....	25.21	"	"
" 1888.....	20.62	"	"
" 1889.....	21.78	"	"
" 1890.....	21.63	"	"

In the experience of the writer the climatic peculiarities of the Riviera invite sudden chills and colds, certain throat troubles, and an exacerbation of some nervous symptoms. But beyond that, all the evil that has been laid at the door of Nice, on the score of its dangerous climate, has been dictated by ignorance, envy, or malevolence. It must stand to reason that a place highly prized by the Romans for its sunshine and dry air, and which for centuries has maintained an excellent reputation as a winter health-resort for all classes of patients, cannot be totally devoid of substantial and permanent advantages. Volumes have been written on the climate of the Riviera. Nice enjoys nothing more nor less than a fair average of Riviera climate. This means that it is not devoid of drawbacks, and that ideal winters are not found there. Nice is more sheltered than some places, but it is nevertheless exposed to the *mistral*, which blows at Nice just as it blows at most other Riviera spots.

It should be borne in mind by invalids and tourists that Nice and the Riviera in general really possess two distinct and different climates, viz., a sea-shore or marine climate, and an inland or mountain climate. It is quite well known that immediate proximity to the sea may induce sleeplessness and other symptoms, denoting too exciting an action on the nervous system. The dry, sunny, inland air is tonic and sedative ; the air in immediate proximity to the shores of the sea is bracing and exciting. The air of the city and its suburbs is often a mixture of the two.

It is thus apparent that a number of local climates are found at Nice, concerning which the resident physicians will inform invalids.

The class of patients likely to derive some benefit from a winter season spent at Nice comprises those in need of sunshine, warmth, dry air, and creature comforts.

Anæmia, chlorosis, scrofula, gout, rheumatism, chronic bronchitis, asthma, catarrhal conditions of the upper air-passages, the early stage of phthisis, chronic Bright's disease, and diabetes may all be more or less favorably influenced by the climate of Nice. The feebleness of old age and exhaustion from over-work or over-indulgence are also among the indications for a season on the Riviera.

In conclusion, it may be borne in mind by the physician that the city of Nice has so many superior attractions and offers so much in the way of amusements and distraction, that it is more largely visited by wealthy semi-invalids (and particularly by Americans) than any other resort on the Riviera. And thus it happens often enough that patients sent elsewhere gravitate toward this gay capital of the Mediterranean littoral without repenting their choice. *Edmund C. Wendt.*

NOTIFICATION OF INFECTIOUS DISEASES.

Among the different measures employed by sanitary authorities for the prevention of the spread of infectious diseases, the notification of the occurrence of such diseases now occupies a prominent place. Municipal authorities especially should have the requisite power everywhere to require immediate notice to be given them of every fresh outbreak of diseases dangerous to the public health in order that such authority may take proper measures for the protection of the community.

The chief advantages of a system of notification lie in the possibility which is thus given to a local board of health to determine the extent of prevalence of an epidemic or a localized outbreak, and to inquire into the local causes which have operated to produce it. The board can then act intelligently in applying the proper remedies for preventing its further spread.

Laws enacted with this object in view have been in force in the older States for many years, but not until within the past ten or twenty years have pains been taken to execute such statutes with such degree of efficiency as to make them really protective. The law requiring the householder to report each case of dangerous disease to the local authority was enacted in Massachusetts in 1792, and that which requires the same duty on the part of the attending physician was enacted in 1827.

Various attempts have been made in England to enact a similar statute, but these efforts were unsuccessful until 1889. By the terms of the law then enacted the notification of infectious diseases to the sanitary authority was made compulsory throughout London, while the principle of local option was applied to all other districts.

During the year in which this bill was under consideration by Parliament, intense opposition had been manifested by many of the members of the medical profession throughout England. Objections were offered not only by the people but also by the medical profession, but the bill passed and finally became a law.

The fallacy of the objections has been abundantly proven by the three years' experience of the towns of England where the Notification Act has been adopted. The notification of each case is made by a certificate furnished by the attending physician, for which a fee of two shillings and sixpence is paid, except in a case where the person giving the certificate is the medical officer of a public institution, when the fee is one shilling.

The diseases to which this act applies are small-pox, cholera, diphtheria, membranous croup, erysipelas, scarlet fever, typhus, typhoid and puerperal fever, and any other infectious disease which may be added to this list by the sanitary authority of a district.

Up to the present year (1892), the act had been adopted in 1,051 districts, having an aggregate population of nearly sixteen millions, to which should be added the population of London and fifty towns in which local acts made it compulsory, making in all a population of 24,012,399 over which the act was in force, out of a total of 29,001,018. In a few towns the sanitary authorities had availed themselves of the power to require notification in the case of measles, Rötheln, chicken-pox, and hydrophobia.

In Massachusetts there can be no doubt that the law relative to notification has been productive of excellent results in the prevention of disease, especially in the cities and large towns. It has furnished the local boards of health with the necessary information relative to the origin of outbreaks of infectious disease, and in many instances enabled them to take timely steps for preventing its further spread. The recent law requiring local boards to keep records upon this important matter, has furnished information as to the prevalence of certain diseases in the principal cities and towns of the State. In the smaller towns it is probable that instances of failure to comply with the provisions of the statute are much more frequent than they are in cities.

In the Twenty-third Report of the State Board of Health of Massachusetts, a table is presented for the first time, giving a summary of the records of such local boards of health as could be obtained in this direction.

From this table it appears that the number of reported

cases and deaths, and the percentages of deaths to reported cases, were as follows:

Reported cases of diphtheria	2,444
Reported deaths from diphtheria	575
Percentage of deaths to reported cases	23.5
Reported cases of scarlet fever	4,517
Reported deaths from scarlet fever	151
Percentage of deaths to reported cases	3.34
Reported cases of typhoid fever	2,414
Reported deaths from typhoid fever	460
Percentage of deaths to reported cases	19.05
Reported cases of measles	5,861
Reported deaths from measles	84
Percentage of deaths to reported cases	1.4

The foregoing percentages may be considered as somewhat larger than the actual percentages of fatalities from these diseases during the year, for the reason that the number of deaths is known, while the number of reported cases is probably less than the actual number.

Similar tables and percentages have also been prepared from the English returns for the same year, in which the ratio of deaths to reported cases was slightly greater in the case of each disease than those of Massachusetts for the same year.

The records of these cases, preserved in the offices of the local boards of health, have proved very serviceable in recent years as an aid in the tracing of the causes and conditions prevailing in local epidemics of typhoid fever, especially where water and milk supplies were involved.

Samuel W. Abbott.

OLD AGE, RECUPERATIVE POWERS OF. The life of man may be broadly divided into three periods, namely, of growth, of maturity, and of decline. These three stages are characterized by sharply defined differences, both physical and mental, which are patent to the most unobserving. Youth is a period of restless growth. The stature is increasing; the bones, the muscles, the blood-vessels, and nerves, all are lengthening and expanding, regularly and evenly; the vital organs are being strengthened and adapted to the work they have to perform in the economy; the reproductive organs and those of special sense are developing; the nervous system is maturing and acquiring, by slow degrees, a more perfect and regulated control over all the functions of animal life; while at the same time the intellectual faculties are slowly unfolding and gaining, step by step, the mastery over the purely physical impulses or unreasoning instinct. In a word, the final scenes of evolution are being again enacted—the animal is becoming human. This period is one of great danger, since the imperfectly formed tissues are extremely vulnerable and sensitive, and are prone to take on excessive reaction in response to comparatively slight insults. Disease kills quickly at this age, for the faculty of sustained resistance is as yet undeveloped. On the other hand, the recuperative forces are very efficient, as we might suppose they would be at a time when the constructive changes are at their period of greatest activity; and when, therefore, acute disease does not kill, recovery from its effects is usually rapid and complete.

The adult is the physically grown man. The process of accretion is at an end, metabolism is in equilibrium, and the anabolic or constructive changes equal, but no longer exceed, the katabolic or destructive. The skeleton is fully formed, epiphyses and apophyses are united; the frame is strongly knit, the muscles are firm; all the organs are in a state of greatest potential activity, and the whole physical complex is most wonderfully controlled and regulated by the matured and perfected nervous apparatus. Although, in the strict sense of the term, growth has ceased, there still remains the potentiality of a modified form of growth which we call repair. By means of this power losses of tissue are made good, worn-out parts are renewed, and a healthy equilibrium is maintained. Ordinarily this recuperative force is sufficient to restore only the losses of normal every-day waste, but it is capable of great extension under certain circumstances and to meet certain emergencies. Overwork or disease often causes an excessive destruction of tissue which would speedily put an end to the individual were anabolism limited strictly to these every-day needs of the economy. But we know that such losses are not irreparable, and that there is a recreative force which quickly restores the normal equilibrium when once the destructive agencies have ceased to act. This reparation, when it occurs from the effects of wasting disease, we call convalescence—growing strong; when the muscles or nervous system are wasted by over-action, we rest them in order to permit of their restoration by anabolic processes, and this rest we call re-creation.

In old age the period of stability is at an end. This stage has been well characterized by Canstatt as the period of involution or of retrograde formation. The metabolic equilibrium has been lost, anabolism no longer keeps pace with katabolism, and so the tissues waste; all the organs, with the exception of the heart and kidneys, diminish in size and perform their functions feebly, if at all; the special senses are dulled; the stature grows less; fatty and calcareous degenerations involve the anatomical elements; the bones become loose in texture and brittle, the muscles waste and lose their power, the skin shrivels, the hair bleaches and falls out—in a word, the characteristic change of old age is one of atrophy. The vital forces are less elastic, are more quickly depressed, and when once seriously lowered seldom return fully to the point where they were before. The recuperative powers, so active in adult life, are impaired, though, as we shall see, less seriously impaired than is commonly supposed. The aged are less exposed to attacks of acute disease than the young or those in middle life, but they are also less able to resist such attacks, at least at their outset; they are more liable to succumb to shock, and their reactive powers are depressed.

There is, therefore, some ground for the apprehension that most physicians feel when called to minister to an old person suffering from disease or injury, and their gloomy forebodings are, it must be confessed, frequently justified by the results. Yet the case is oftentimes less desperate than we are wont to assume, and not uncommonly the patient runs greater danger from the utter lack of hope with which his medical attendant and friends regard his condition than he does from the disease itself. The physician who looks upon an old and enfeebled man, suffering from pneumonia or from a fracture of the neck of the femur, as one doomed to speedy dissolution may be led thereby to neglect measures which he would institute in the case of a younger person. He is more or less influenced in his management of the case by the feeling that all that he can do is to relieve pain and to smooth, as far as possible, the sufferer's path to the grave. That this fear is not always justified by the results, however, must have occurred to many, for there can be few practitioners of long experience who have not seen cases which have been practically abandoned as hopeless recover, and recover not merely by chance but as the result apparently of carefully instituted treatment. It may be said that these are the exceptions that occur to every rule, that the old people would have recovered in any event, and that the treatment had nothing to do with the result. Even so; but the fact that they did recover, whether in consequence, or in spite, of treatment, proves that all old patients do not necessarily die when a serious disease attacks them, and it should serve to impress upon us the wisdom of taking into consideration the chances of recovery in every case, no matter how seemingly hopeless, and of doing what we can to favor them. The writer meets frequently an old man of nearly ninety years, who is going about to-day a cripple in consequence of a badly united fracture of the thigh. He fell on the ice and broke his femur some three years ago, and because he was so old and decrepit his medical attendant contented himself with simply retaining the leg in a com-

fortable position, making no attempt to secure perfect coaptation of the ends of the bone, thinking that it would be cruel to torture a dying man. In spite of the non-apposition of the fragments, union occurred as rapidly as if the patient had been forty-three instead of eighty-three years old, and now the poor old body is condemned to drag along the few remaining years of his none too joyous life in still greater discomfort, simply because his surgeon thought him too old to mend his broken frame.

The attention of the writer was drawn to this facility of repair, in old people, several years ago, at the time when he first took up the study of senile pathology and therapeutics, upon assuming medical supervision of a home for the aged in this city. He then shared the pessimistic views of most people, medical as well as lay, concerning the outcome of pneumonia in the aged, and felt that when once a diagnosis of the case had been established, about all had been done for the patient that the most conscientious physician could do. But when several of the inmates of the institution, whose ages ranged from seventy to eighty-five years, and who were incontestably suffering from pneumonia, falsified my prognosis by recovering instead of dying, my views began to change. I then commenced to treat the old people a little more carefully because more hopefully, and was soon as gratified as I was astonished to find that death was not the rule by any means. During the following two years there were forty-four cases of croupous pneumonia in the home, and of this number no less than twenty-seven recovered. There were seven cases of sudden death, for which no cause was evident, and which were very probably examples of that insidious and undiagnosable form of pneumonia sometimes found at autopsies on the aged; but even after adding these to the number given above, we find that there were twenty-seven recoveries out of fifty-one cases, or over fifty per cent., a great improvement over the seventy-five or eighty per cent. given by some writers on old age as the mortality from pneumonia in persons over seventy years old. These cases were not at all mild, some of them being of most disheartening gravity, and no claim is made for any specially efficacious form of treatment; the result was attributable simply to the kind nursing of the Sisters and to the recuperative powers inherent in the tissues of the aged patients.

But instances of this recuperative power were not confined to those suffering from pneumonia, and my surprise was continually excited by the repeated observation of recoveries from other grave diseases, and after injuries that would have been serious even in the young. Fractures, when not intracapsular, healed rapidly, ulcers needed only to be encouraged by gentle stimulation and cleanliness, carbuncles were not always fatal, and the wounds left by them cicatrized kindly; bronchitis and diarrhœa were hardly more serious maladies than if they had occurred in the middle-aged, and even cerebral hemorrhage did not always kill, nor did it invariably leave behind a permanently incapacitating paralysis.

About this time Professor George M. Humphrey, of Cambridge, began to publish a series of articles on Old Age in the *British Medical Journal*. His papers were based on the results of a collective investigation on "the present condition, habits, circumstances, etc., of aged persons," undertaken by the British Medical Association. Perhaps the most interesting fact concerning old people brought out by this investigation was that of the astonishing power which they possessed of recuperation after injury or disease, and this was made the subject of several of Professor Humphrey's articles. He found many cases recorded of fractures and other injuries in persons advanced in years, in which repair took place as quickly as it normally does in the middle-aged, and he also met with many instances evincing the possession by old people of astonishingly great recuperative powers after severe attacks of bronchitis, pneumonia, apoplexy, and other grave illnesses. The most remarkable were perhaps the recoveries from brain affections. There were reports of twenty-five cases "in which brain attacks associated with paralysis, in most instances hemiplegia, and in some with convulsions and unconsciousness, were in greater or less degree recovered from. In some the recovery was complete. One man had three attacks of paralysis at eighty-two, eighty-five, and eighty-six; and one woman, in addition to several attacks of unconsciousness, had left hemiplegia and convulsions at seventy-eight, paralysis of the left hand at eighty-two, and severe apoplexy at eighty-nine, after which she was able to get about again, though with weakened mind and a liability to epilepsy."

Since that time, namely, during the past ten years, there seems to have been quite a general awakening to the fact that the power of repair is not lost in proportion as senile atrophy progresses, and the literature on the subject is now becoming fairly voluminous. The titles and authors of a number of journal articles on the recuperative powers of old age will be found below in the bibliographical list appended to this essay; but the reports of individual instances of recovery from disease or injury are too numerous even to be mentioned here, and it will suffice to refer very briefly to a few only of the cases which I have found recorded in medical literature.

Among the diseases belonging to the department of internal medicine by far the most frequently noted is croupous pneumonia, a fact which need occasion no surprise when we consider that this is one of the most common causes of death in old people in our northern climate. I have already referred to my own unpublished cases to the number of fifty-one, among which there were twenty-seven recoveries. Seven of these latter were over eighty years of age, thirteen were between seventy and eighty, and the remaining seven were between sixty-five and seventy. In six cases there was consolidation in both lungs. One patient, an old woman, eighty-nine years of age, had an attack in each of two successive years, the second one involving a good portion of both lungs, yet she lived to die from the effects of falling out of bed three years later. Several of them were extremely feeble, seeming scarcely to have vitality enough to keep alive before contracting the disease, yet convalescence, when once the crisis was passed, appeared to progress as steadily and as favorably as one would expect it to do in a robust youth.

Dr. Giuseppe Lapponi reported, in the *Raccoglitore Medico* for January 10, 1887, a case of recovery from pneumonia in a woman, seventy-four years of age, who was the subject of chronic renal disease, the uræmic condition being the occasion of an apyretic state which served to mask for a time the existence of the pneumonia. The physical signs, however, left no room for doubt as to the diagnosis. Despite the very grave complication furnished by the kidney lesion, resolution of the pneumonic process was complete.

In an article in the *British Medical Journal* for June 12, 1886, Dr. George M. Humphrey relates at some length the case of Miss Hastings, aged one hundred and four years, the sister of Sir Charles Hastings, the founder of the British Medical Association. She had facial erysipelas and pneumonia, from which she recovered perfectly, when she was between ninety-nine and one hundred years of age. When within six weeks of her one hundred and fifth birthday, she had a severe attack of pneumonia, involving the bases of both lungs, but she recovered completely, the lung clearing up well and leaving only a chronic bronchitis from which she had suffered for many years.

Dr. W. Washburn, in an article in the *Medical Record* for February 18, 1893, on the value of opium in the treatment of shock and pneumonia, mentions a case of recovery from the latter in the person of a patient seventy-four years old. In this instance the patient had at first two carbuncles, then erysipelas, and finally pneumonia. The details of treatment of the case are not given, beyond the statement that small repeated doses of opium were exhibited.

Sir Andrew Clark reported, at a meeting of the Medical Society of London (*British Medical Journal*, December 20, 1884), a remarkable case of intermitting or relapsing pneumonia in a man, eighty-two years old, who

had passed through a similar attack at the age of seventy-five. The patient was ill for seven weeks, during which period he passed through nine or ten severe rigors and had six successive attacks of pneumonic exudation, finally making a perfect recovery.

My notes, personal and gleaned from periodical literature, contain the histories of a large number of cases of recovery from attacks of other severe illnesses, chiefly bronchitis, gastritis, diarrhœa, and intestinal obstruction, the reports of which would, however, extend this article beyond due limits and must therefore be omitted. Many of them are, nevertheless, of striking interest, and all furnish indubitable proof of the fact that old age offers in itself no bar to recovery from acute disease, and they show the unwisdom of abandoning hope in even seemingly desperate cases among the aged.

The most convincing evidence of the powers of repair inherent in the tissues of old people is furnished by the histories of injuries and of surgical operations. Hospital records are full of cases of recovery after operation for hernia, vesical calculus, or enlarged prostate, occurring in persons over seventy years of age, and almost every surgeon can recall many such instances in his own practice. Nearly thirty years ago, Dr. Daniel Donovan, of Skiberbeen, sought to draw the attention of the profession to the remarkable tolerance and recuperative powers possessed by the aged, and urged upon his colleagues the necessity for greater boldness in operating in such cases, reporting several successful instances from his own experience in support of his position. Since that time, Humphrey, Graham, Blum, and others have written in the same strain, but their teachings are so opposed to the general impression among surgeons that it is doubtful whether they have as yet had much influence in modifying the prevailing opinion. As Humphrey remarks: "These inferences (of the reparative powers of the aged after fractures, wounds, etc.) are so contrary to preconceived notions, indeed, to probabilities, that it takes some time and effort and frequent repetition to obtain for them a fair measure of acceptance." The fact did not escape the keen observation of the late Professor Gross, who asserted, in his "System of Surgery," that age is no barrier to union after fracture; but most other surgical authorities still incline to the contrary view. For example, in one of the latest works on surgery ("An American Text-book of Surgery," 1892), we find it stated that "old age is likewise a factor for evil. After forty, patients bear operations increasingly less and less well as their age advances," and several other writers of equal authority express themselves in much the same fashion. They are, to a certain extent, right in this discouraging view, for it is undeniable that the aged are more prone to suffer from shock after severe injuries and surgical operations, and also that their wounds are more liable to slough; there is, too, greater danger of cardiac and respiratory disturbances during the administration of a general anæsthetic, whether it be ether or chloroform. But, these dangers aside, the results of operations are almost as favorable in the old as in the young and middle-aged, and repair proceeds in them with at times amazing rapidity. The following cases, selected from a number scattered throughout periodical literature, bear testimony to this fact. Reports of operations upon old men for enlarged prostate or for the removal of vesical calculi, as also cases of operation for incarcerated hernia, have been omitted, partly because they are operations of necessity and must be performed whatever the risk, and partly because they are of such frequent occurrence that instances of recovery subsequent to them are within the knowledge of everyone. Indeed, it is strange that the frequently successful outcome of these cases seems to have had little or no influence in modifying the surgical distrust of old people in general, the fact that they often recover rapidly after the release of an incarcerated loop of intestine, notwithstanding the shock, appearing to have seldom suggested the thought that they may recover equally well after the removal of a cancer of the breast or other capital operation. No attempt has been made to arrange the following cases chronologically or in the order of their importance, the only classification being according to the nature of the operation or injury.

Amputation of the Breast.—Dr. Prégaldino (*Annales de la Société de Médecine de Gand*, October, 1886). Woman, ninety-three years of age; chloroform anæsthesia; union by first intention, except at two points where the drainage-tubes were inserted.

John A. Macdougall (*British Medical Journal*, October 11, 1884). Woman, eighty-six years of age; wound became septic, but the patient made an excellent recovery.

Daniel Donovan (*Dublin Medical Press*, August 24, 1864). Woman, eighty-four years of age; wound healed rapidly.

Thomas Annandale (*Edinburgh Medical Journal*, March, 1872). Amputation of the breast and removal of the axillary glands for cancer in a woman seventy years of age.

N. F. Graham (*Medical News*, February 7, 1891). Removal of the right breast for cancer in a woman seventy-one years of age; recovery rapid.

Amputation of the Arm or Leg.—N. F. Graham (*loc. cit.*). Amputation of the leg for senile gangrene in a man ninety-two years of age.

Daniel Donovan (*Dublin Medical Press*, September, 1855). Man, seventy-one years of age; amputation of the leg for senile gangrene.

The same (*Dublin Medical Press*, August 24, 1864). Amputation of the hand for cancer in a woman one hundred and one years of age; union by first intention nearly throughout.

Thomas Annandale (*loc. cit.*). Amputation through the condyles of the humerus for a cartilaginous tumor of the forearm in the case of a woman seventy-four years of age.

John A. Heatly (*New York Medical Journal*, June 28, 1890). A case of pyæmia in a man seventy-one years of age, requiring amputation of the forearm; healing by first intention.

John Ewens (*Lancet*, July 21, 1877). Amputation of the finger for cancer in a woman, a confirmed tippler, eighty-seven years of age; union by first intention.

Richard Jarrot (*Charleston Medical Journal and Review*, May, 1849). Amputation of the leg for gangrene in a man one hundred and two years of age.

George Owen Willis (*British Medical Journal*, November 27, 1886). Amputation of the forearm for epithelioma in a woman eighty-six years of age.

James Cantlie (*British Medical Journal*, October 30, 1886). Amputation of the leg for gangrene in a woman eighty-two years of age.

Harrison Cripps (*British Medical Journal*, May 9, 1885). Amputation of the leg for gangrene in a patient sixty-five years of age.

Dr. Atherton (*Canadian Practitioner*, September, 1887). Amputation through the junction of the middle and lower thirds of the thigh for gangrene in a man sixty-eight years of age.

F. Faulder White (*British Medical Journal*, February 8, 1890). Amputation of the arm for disease following injury to the elbow-joint in a woman eighty years of age.

Bone Operations.—Thomas Annandale (*loc. cit.*). Primary excision of the elbow-joint for compound comminuted fracture in a woman seventy-four years of age.

The same. Excision of the upper jaw for removal of a medullary tumor in a man seventy years of age.

The same. Excision of the lower jaw and of the submaxillary gland for cancer in a man seventy-four years of age.

V. Hutchinson (*Lancet*, August 4, 1877). Resection of the forearm for gangrene in a man nearly ninety years of age.

Dr. Eustache (*Journal des Sciences Médicales de Lille*, July 29, 1887). Excision of the lower jaw for sarcoma in a man seventy-five years of age.

Removal of Tumors from Soft Parts.—Henry A. Lediard (*Lancet*, November 23, 1889). Lympho-sarcoma in a man sixty-two years of age; recurrence in the cervical glands; excision, and finally complete recovery.

N. F. Graham (*loc. cit.*). Two cases of wedge-shaped excision of the lower lip for epithelioma, in men respectively seventy-four and eighty years of age; union by first intention.

John Evans (*Lancet*, August 1, 1868). Wedge-shaped excision of the lower lip for epithelioma in a man seventy-five years of age.

The same (*Lancet*, February 22, 1873). A similar operation in a man sixty-five years of age.

Thomas Annandale (*loc. cit.*). Excision of one-half of the tongue for epithelioma in a woman seventy-one years of age.

The same. Removal of a large portion of the cheek, lip, and nose for epithelial cancer in a patient seventy-two years of age.

The same. Removal of a large fatty tumor from the back of the neck in a man seventy-three years of age.

The same. Removal of a large fatty tumor from the inner aspect of the thigh in a woman seventy-one years of age.

John Ewens (*Lancet*, July 21, 1877). Removal of a cancer of the left cheek in a man seventy-eight years of age.

G. B. Ferguson (*Lancet*, March 11, 1876). Removal of a melanotic sarcoma originating in the sheath of the sartorius muscle in a man seventy-five years of age; after an attack of erysipelas, perfect recovery followed.

Ovariotomy.—Fancourt Barnes (*Provincial Medical Journal*, April 2, 1888). Three cases in women, aged respectively sixty-five, sixty-seven, and seventy years of age.

Thomas Legaré (*Journal of the American Medical Association*, August 31, 1889). A case with extensive adhesions in a woman eighty years of age.

John Homans (*Medical Record*, May 5, 1888). Case in a woman eighty-two years and four months of age.

Haywood Smith (*Lancet*, December 24, 1892). Case in a woman, seventy-eight years of age.

Joseph Tabor Johnson (*Virginia Medical Monthly*, December, 1888). Case in a woman sixty-four years of age.

The same (*Virginia Medical Monthly*, December, 1892). Three cases at sixty-seven, sixty-eight, and sixty-seven years respectively. In the same article the author gives a table of thirty-eight cases, collected from current literature, of ovariotomy in women between sixty-seven and eighty-two years of age, with but two deaths.

J. Rutherford Morrison (*Lancet*, January 21, 1893). Five cases of cœliotomy (four ovariotomy) in women, aged respectively seventy, seventy-four, seventy-two, seventy-seven, and seventy years; all recovered from the operation; one died nearly two months after the operation from the results of appendicitis; one had extensive malignant disease, but recovered from the exploratory incision, dying over two months later from the cancer; the three uncomplicated cases of ovariotomy recovered perfectly, returning to their homes within a fortnight.

Wounds and Fractures.—John A. Macdougall (*British Medical Journal*, October 11, 1884). Fracture of the left forearm, with an extensive bruise of the face, resulting from a fall, in a woman between seventy and eighty years of age.

T. Sydney Short (*British Medical Journal*, August 3, 1889). Fracture of the sternum, with double pleuropneumonia, in a man sixty-four years of age.

Hoadly Gabb (*British Medical Journal*). Fracture of the coracoid process in a man seventy-four years of age.

Thomas F. Raven (*Lancet*, August 6, 1887). Intracapsular fracture of the neck of the femur in a woman, sixty-nine years of age; osseous union.

N. Senn (*Journal of the American Medical Association*, August 3, 1889). Eight cases of intra-capsular fracture of the neck of the femur in persons from fifty to sixty-eight years of age; recovery of the use of the limb with, in some cases, hardly a limp.

A. M. Powell (*St. Louis Medical and Surgical Journal*, June, 1889). Fracture of the arch of the seventh cervical vertebra in a man sixty-eight years of age.

N. F. Graham (*loc. cit.*). Fracture of the forearm in a woman, ninety-one years of age; union complete in six weeks.

The same. Fracture of the neck of the femur in a woman, eighty-one years of age; recovery in ten weeks with a useful limb, and only one and one-half inch shortening.

The same. Fracture of the radius in a woman, seventy-six years of age; good union in six weeks.

The same. Axe-wound of the face, cutting through the bridge of the nose deep into the maxilla and opening into the mouth, in a man, eighty-seven years of age; much loss of blood; the detached portion of the nose and face was turned up and united by sutures; union was perfect, and the man was out of bed in four days.

J. Fayrer (*Medical Times and Gazette*, December 7, 1867). Fracture of the bones of the leg in a man ninety-six years of age; rapid union without any constitutional disturbance.

There are many other cases among my notes of removal of foreign bodies from the œsophagus and from the bladder, spontaneous amputation in senile gangrene, cure of popliteal aneurism, recovery from carbuncle and from the effects of serious injuries of the soft parts, etc., occurring in persons aged from sixty-five to ninety-five years. These all bear testimony to the remarkable tolerance to traumatism of the tissues of old people, and to the power of repair inherent in them; but it would be wearisome to record every instance of the sort, and those above given are sufficient to demonstrate that the aged possess a facility for repair much greater than we are accustomed to credit them with.

Various theories have been offered by the writers above mentioned in explanation of this recuperative power in the aged. Thus it has been attributed to the fact of a lessened nerve-susceptibility, or to a sort of disconnection between the different organs in consequence of which disease in one part affects more remote regions but little and causes therefore slight constitutional disturbance; this leaves the vis medicatrix free to exert all its reparative force on the affected organ or member. Graham says that the cellular elements, though diminished in size, still retain their physiological characteristics, and that they will return as certainly in the aged to the embryonic state, when a part is inflamed, as they will in the young or middle-aged; and it is in this fact of the retention by the cellular elements of their normal physiological condition that is to be found the explanation of the quick recovery of old people from serious injury or disease.

But after all, it ought not to be so surprising that aged people often recover from the effects of injury or disease. They must have been endowed at birth with considerable resisting power against the onslaughts of disease, otherwise they would have been cut off earlier. It is, as a rule, the fittest physically who survive, and it is therefore only reasonable to expect that this resisting power should continue to the end, until the long sleep comes naturally as the normal physiological termination to a well-lived life. *Thomas Lathrop Stedman.*

OPHTHALMOMETER.*—An instrument for measuring the curvature of the refracting surfaces of the eye.

* The writer desires particularly to acknowledge his indebtedness to Dr. John Green, of St. Louis, for assistance most kindly rendered in revising articles "Ophthalmometer" and "Shadow-Test" for the press. In the course of this revision many infelicities of diction, due to the writer's brief acquaintance with the English language, have been eliminated, and some additions have been suggested and adopted with a view to a clearer and fuller presentation of the subject.—Carl Koller.

Thomas Young (1801)[1] was the first investigator to attempt accurate measurements of the curvature of the cornea in the living eye. By measuring the diameter and the prominence of the cornea, he found the chord and versed-sine of an arc of a corneal meridian; from these data he calculated the radius of curvature. Young's estimate of the curvature of the cornea agrees very closely with the results which have since been obtained by more refined methods.

Kohlrausch (1840)[2] measured the image of a distant object viewed by reflection at the anterior surface of the cornea, as in a convex mirror, and thus laid the foundation of ophthalmometry in the modern sense. The object used by Kohlrausch was a pair of candle flames placed behind small openings in an opaque screen. The images of the two bright points were viewed through a small astronomical telescope, constructed for observing at a distance of from two to three feet, and their positions marked by two adjustable spider-lines in the eye-piece. The length of the image (distance separating the images of the two points of light) was then read, through the telescope, on a finely divided scale placed as nearly as possible at the distance at which the image had been observed.

Now the object and the image lie at conjugate foci of the cornea, considered as a convex mirror, and the relations of the two focal distances is expressed by the equation

$$\frac{1}{f'} - \frac{1}{f} = \frac{2}{r};$$

or

$$r = 2f \cdot \frac{f'}{f - f'}; \qquad (1)$$

in which

r = the radius of curvature of the cornea.

f = the distance of the object from the surface of the cornea.

f' = the distance of the image from the surface of the cornea.

As the observing distance is taken at between two and three feet, and the object is stationed at as great or at a greater distance, f is quite large in comparison with f'; it is admissible, therefore, without sensibly affecting the accuracy of the equation, to disregard f' in the denominator of (1) and to write the equation in the simplified form

$$r = 2f \cdot \frac{f'}{f} = 2f'.* \qquad (2)$$

Again, the length of the object is to the length of the image in the ratio of their respective distances from the centre of curvature of the convex mirror (cornea).

Designating these distances by g and g' respectively, we have

$$\frac{g'}{g} = \frac{\text{length of image}}{\text{length of object}}.$$

But

$$g' = r - f$$

and

$$g = r + f$$

whence

$$\frac{r - f}{r + f} = \frac{\text{length of image}}{\text{length of object}};$$

or

$$r - f = (r + f) \cdot \frac{\text{length of image}}{\text{length of object}}. \qquad (3)$$

* To test the error involved in the use of this simplified equation, compare the values of r derived from (1) and (2) in a special case. For example:

Let $f = .8$ metre $= 800$ millimetres,
Let $f' = 4$ millimetres,

then by (1)

$$r = 1600 \cdot \frac{f'}{796} = 2.01f';$$

and by (2)

$$r = 1600 \cdot \frac{f'}{800} = 2.00f'.$$

The value of r by (2) is therefore too small by $0.01f' = 0.01 \times 4$ millimetres $= 0.04$ millimetre, which is within the limit of error in observation.

In the right hand member of (3) neglecting r, which is small compared with f, and in the left hand member of (3) substituting for f' its value $\frac{1}{2}r$ derived from (2) we have, as a sufficiently close approximation, the simplified equation

$$r = 2f \cdot \frac{\text{length of image}}{\text{length of object}}.* \qquad (4)$$

The results obtained by Kohlrausch, also by Senff (1846),[3] who carried the investigation somewhat farther, correspond very closely with measurements which are now generally accepted. The later development of ophthalmometry has been in the direction of perfecting the instrument for purposes of scientific investigation, and of adapting it to clinical use.

The ophthalmometer was perfected, as an instrument of scientific research, by Helmholtz (1854).[4] With the addition of a large graduated circle, arranged to carry lamps, it was employed by Donders and Middelburg to measure the curvature of the cornea in different meridians.

The ophthalmometer of Helmholtz is essentially an adaptation of the heliometer of Clausen (1841).[5] A divided plate of thick glass with parallel surfaces, is mounted in a cubical box fixed in front of the objective of a small astronomical telescope constructed for observing at a distance of from 0.5 metre to 1 meter, so that each half of the glass plate covers half of the objective. The two halves of the divided plate are arranged to turn in opposite directions on a common axis at right angles to the axis of the telescope, and the amount of rotation is read to tenths of a degree on a graduated disk fitted with a vernier. So long as the two halves of the glass plate are in the same plane, perpendicular to the axis of the instrument, an object seen through the telescope appears without displacement and single, but any rotation of either half of the plate gives rise to a displacement of the image formed by the corresponding half of the objective, and this displacement increases with the rotation. As the two halves of the plate are rotated simultaneously in opposite directions the displacement of the images is also in opposite directions, and the total displacement is double what it would be if either half of the plate were rotated separately through the same angle.

The object (three points of light disposed in a row) as seen by reflection at the surface of the cornea, is focussed by the telescope through the glass plates in the zero position—*i.e.*, with both plates set at right angles to the line of vision. The graduated disk is then turned until the two images are seen touching each other, but not overlapping, in which position of the plates the displacement of each image is exactly equal to half the length of the image. The amount of displacement (x) of either

* To test the error involved in the use of (4) compare the values of r derived from (3) and (4), in a special case. For example, as in the previous note:

Let $f = .8$ metre $= 800$ millimetres,
Let $f' = 4$ millimetres.

Then by (3) [using for r in the right hand member and for f' in the left hand member their values as given by (1),]

$$r - \frac{r}{2.01} = (800 + 8.04) \cdot \frac{\text{length of image}}{\text{length of object}} \text{ millimetres},$$

whence

$$r = 1608.08 \cdot \frac{\text{length of image}}{\text{length of object}} \text{ millimetres},$$

and by (4)

$$r = 1600 \cdot \frac{\text{length of image}}{\text{length of object}} \text{ millimetres}.$$

The value of r by (4), is therefore too small by

$$\frac{8.08}{1600} = 0.005 = \text{about } \tfrac{1}{2}\% \text{ per cent.}$$

It should be further remarked that the use of the equation,

$$\frac{1}{f'} - \frac{1}{f} = \frac{2}{r},$$

is permissible only on the assumption that the diameter of the convex surface at which rays are reflected to form the virtual image is small in comparison with the radius of the sphere. This implies that the image must be small in comparison with the radius of curvature of the cornea, or, what amounts to the same thing, that the object must be small in comparison with its distance from the observed eye.

image depends on the index of the refraction (n) of the glass of which the plate is made, the thickness (h) of the glass plate, and the angle (ϕ) through which the plate has been rotated as expressed in the equation

$$x = h \cdot \frac{\sin(\phi - \phi')}{\cos \phi'},$$

the value of ϕ' being dependent on that of ϕ, as expressed in the equation,

$$\sin \phi = n \cdot \sin \phi';$$

as the displacement of each image is equal to half the length of the image, we have

$$\text{length of image} = 2x = 2h \cdot \frac{\sin(\phi - \phi')}{\cos \phi'}. \qquad (5)$$

In practice all calculation is dispensed with by making use of a table of successive values of $2x$ corresponding to different readings of the ophthalmometer, as ascertained by experiment.

As the distance of the object is quite large in comparison with the radius of curvature of the cornea, it is admissible to calculate the latter by the use of the simplified equation

$$r = 2f \cdot \frac{\text{length of image}}{\text{length of object}}. \qquad (4)$$

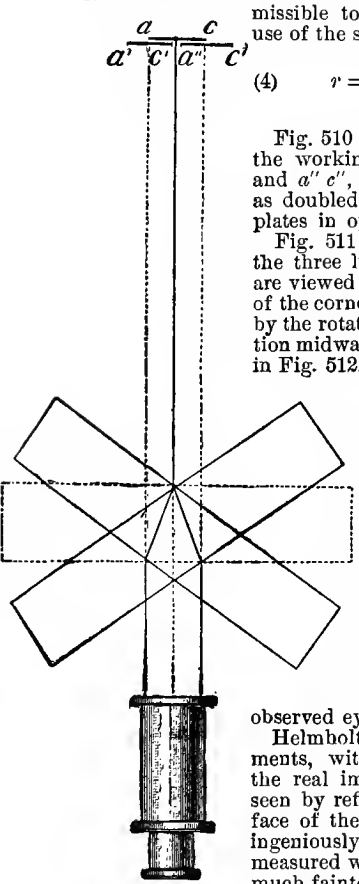

Fig. 510.

Fig. 510 shows the arrangement and the working of the glass plates, a' c' and a'' c'', representing the image a, c, as doubled by the rotation of the two plates in opposite directions.

Fig. 511 shows the arrangement of the three lights, whose double images are viewed by reflection at the surface of the cornea; the image of 1 is brought by the rotation of the plates into a position midway between 2 and 3, as shown in Fig. 512.

It will be seen from (5), also from inspection of Fig. 510, that the size of the image is determined by the amount of rotation of the plates as indicated by the reading of the graduated disk, and is independent of the observing distance; also that, from the principle of construction of the ophthalmometer, the measurements may be made with great accuracy and without being materially impeded by slight movements of the observed eye.

Helmholtz also made direct measurements, with his ophthalmometer, of the real image of a pair of lights as seen by reflection at the posterior surface of the crystalline lens, and by an ingeniously devised indirect method he measured with the same instrument the much fainter virtual image formed by reflection at the anterior surface of the lens. By repeated measurements made upon the same eye in a state of accommodative relaxation and in accommodation for the near, he obtained the necessary data for calculating the radii of curvature of both surfaces of the lens in each of these two conditions. The measurements of Helmholtz were repeated with some modifications of the technique by H. Knapp (1860).[6] Knapp also measured the curvature of the cornea, mostly in the horizontal and vertical meridians, in a series of cases of astigmatism (1862).[7]

To adapt the ophthalmometer to the measurement of the curvature of the cornea in any required meridian, Donders and Middelburg (1863)[8] added a graduated circle, bearing lamps (see Fig. 513). They measured the curvature of the cornea in a large number of eyes in twelve

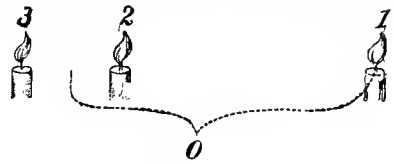

Fig. 511.

meridians, thereby adding greatly to what had been previously known regarding the different forms of astigmatism.

Coccius (1867)[9] substituted a fixed plate cut from a

Fig. 512.

doubly refracting crystal of Iceland spar for the movable glass plates used by Helmholtz. The amount of displacement of the image formed by the extraordinarily refracted rays is determined by the thickness of the

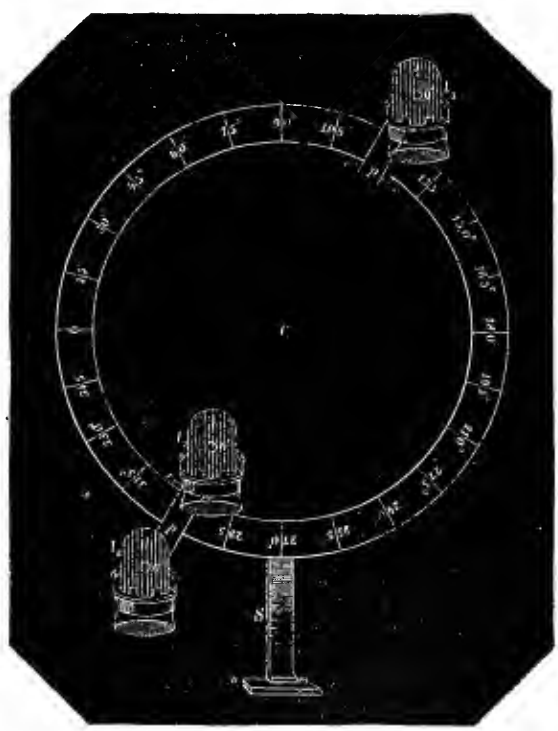

Fig. 513.

plate, and is constant; the size of the object (distance separating the lights) is therefore varied, until the two images are seen to touch each other without overlapping.

The radius of curvature of the cornea is found from the simplified equation.

$$(4) \qquad r = 2f.\ \frac{\text{length of image}}{\text{length of object}}$$

The ophthalmometer of Javal-Schiötz (1881)[10] is especially designed for the clinical investigation of the curva

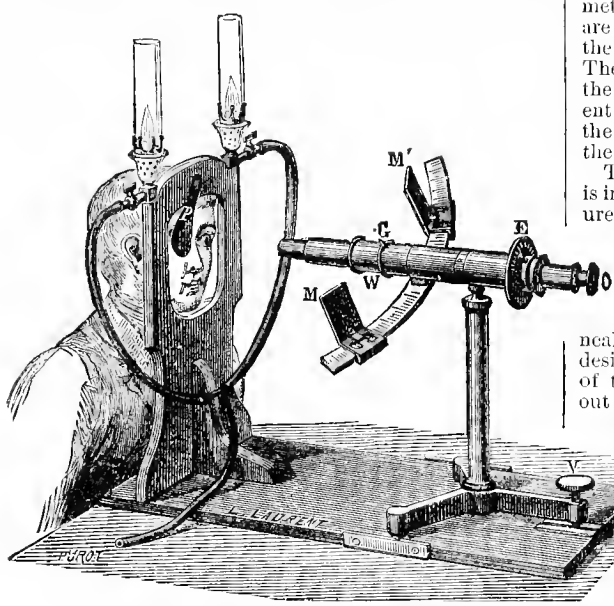

FIG. 514.—Ophthalmometer of Javal-Schiötz, Original Model.

ture of the cornea in all meridians, and is admirably adapted to its purpose. Two strongly illuminated targets (*mires*) of white enamel replace the lights, and the doubling of the image is effected by means of a doubly refracting prism of Iceland spar, which is achromatized, and at the same time a little more than neutralized for the ordinary rays by the addition of a prism of flint glass turned in the opposite direction. With this construction of the prism, the two images of the pair of targets, formed, the one by the ordinary and the other by the extraordinary rays, are displaced equally in opposite directions; the aggregate displacement of the images for the distance at which the eye is observed, is three millimetres. The two targets, MM', Fig. 514, are arranged to slide on a graduated arc of .35 metre radius, turning with the tube of the telescope. The head of the patient is supported by the head-rest, so that the centre of curvature of the cornea shall lie approximately at the centre of curvature of the arc. A more exact adjustment of the distance is then secured by moving the telescope, with its stand, until the doubled images of the two targets are seen sharply defined by reflection at the surface of the cornea; the telescope is constructed for distinct vision at the distance of the image, which is formed about four millimetres behind the centre of the cornea. The doubly refracting prism is in the part of the tube marked GW, and the meridian in which the arc and targets stand is read on the graduated disk at E. The eye under examination is directed upon the end of the telescope; the other eye is covered by the pivoted screen P.

As the effect of the doubly refracting prism (at the constant distance, $f = .35$ metre, of the targets from the eye) is to separate the two images exactly three millimetres, it is evident that when the length of the object (chord M M', separating the outer sides of the two targets) is so adjusted as to allow the two images to touch each other without overlapping, the length of the image must be just three millimetres. We have then, approximately,

$$(4) \quad r = 2f.\ \frac{\text{image}}{\text{object}} = 700.\ \frac{3}{\text{chord M M'}}\ \text{millimetres.} = \frac{2100}{\text{chord M M'}}\ \text{millimetres.}*$$

It will be observed that in this solution, $2f$ ($=2 \times .35$ metre $= 700$ millimetres) and *image* ($= 3$ millimetres) are constants, consequently r (the radius of curvature of the cornea) is an inverse function of the chord M M'. The length of this chord is read from the graduation on the arc. The radius of curvature of the cornea in different meridians may be calculated from measurements of the chord M M', made after turning the telescope, with the arc and targets, about its axis.

The great value of the Javal-Schiötz ophthalmometer is in its remarkable adaptation to the detection and measurement of corneal astigmatism, and for such examination it has won general recognition as indispensable to the ophthalmic practitioner. In astigmatism the essential thing to be considered is the difference in refraction in the two principal meridians, and it is for the measurement of such differences in the corneal curvature that the instrument has been especially designed. In the use of the ophthalmometer the length of the object (chord M M') remains unchanged throughout the observation of the eye in its two principal meridians, and it is only the difference in the length of the image when the arc is adjusted successively for the corneal meridians of greatest and least curvature, that is regarded. The observation consists in simply noting the amount of overlapping of the two images in the second position of the arc, after having first brought them into exact contact in the first position.

The device for reading the amount of overlapping of the images is shown in Fig. 515. The outer side of one of the rectangular targets is cut in the form of steps of such width that each step approximately represents a difference of corneal curvature corresponding to 1 D of ocular refraction.†

* It will be remarked that, by the construction of the Javal-Schiötz ophthalmometer, the distance of the targets from the observed eye is rather small, and the image is rather large in comparison with the radius of curvature of the cornea (see page 702, foot note). In the use of equation (4) there is, therefore, a considerable margin of error, though not enough to detract from the usefulness of the instrument in clinical work.

It will be remarked that r, by this solution, is the radius of a circular arc whose chord measures three millimetres, which arc is assumed to be of the same curvature as a section of the corneal surface by a plane passed through the visual axis and the axis of the telescope. But the configuration of the cornea is approximately that of a segment of a prolate ellipsoid, and supposing the axis of this ellipsoid to coincide with the axis of the telescope, r will be the radius of a circle whose curvature is equal to that of the elliptical section of the cornea at the two points in which the direction of the reflecting surface determines the length of the image, *i.e.*, at two opposite points on the ellipsoid each one and a half millimetres distant from its axis. Under these conditions it is evident that r will be greater than the radius of curvature of the cornea at its centre.

As a rule, the visual axis does not coincide with the axis of the corneal ellipsoid, but makes an angle with it (angle α), which angle is sometimes as great as 12°. The axis of curvature of the cornea is, therefore, not ordinarily in a line with the axis of the telescope, and the two points in which the direction of the corneal surface determines the length of the image are not symmetrically placed with reference to the axis of the ellipsoid. As the curvature of the ellipsoid at these two unsymmetrical points is unequal, it cannot be represented by a spherical surface. In any case, however, the value of r by equation (4) is greater than the radius of curvature of the cornea at its centre.

† Inasmuch as different eyes present considerable variation in corneal curvature, necessitating a corresponding variation in the separation of the targets in order to bring their images into exact contact, it is evident that a step on the target does not always represent the same fractional part of the chord M M'. In the case of a relatively flat cornea the targets must be set nearer together, and each step will then represent a larger fractional part of the chord M M'; conversely, when the cornea is of greater than average curvature the targets must be set wider apart, and each step will then represent a smaller fractional part of the same chord. It follows that in the former case each overlapping step in the image must represent somewhat more, and in the latter case somewhat less, than 1 D of corneal astigmatism. It is well, therefore, always to note the length of the chord M M', so that a correction can be made for it if deemed necessary.

The number of overlapping steps is taken as the number of dioptries of astigmatism attributable to inequality of curvature of the cornea in its two principal meridians.

Fig. 516 shows the doubled images of the targets in the position of contact; in Fig. 517 the same images are

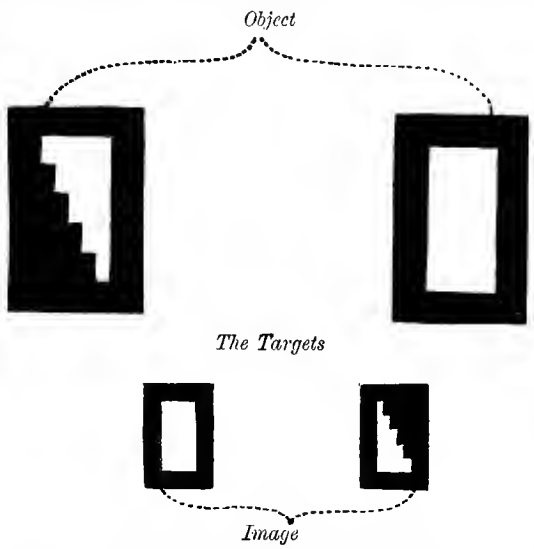

Fig. 515.—Corneal Image as seen Through the Telescope without Intervention of a Prism of Iceland Spar.

shown with two steps overlapping, indicating 2 D of corneal astigmatism. It will be observed that in both these positions the images are rectangular, also that they lie exactly in the same line.

This rectangular form and linear direction of the images of the four targets is seen whenever the curvature of

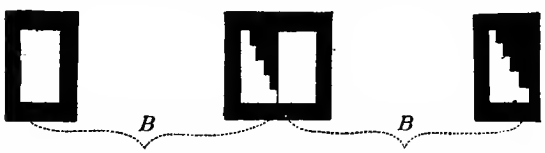

Fig. 516.—Corneal Image as Seen Through Telescope and Prism. Double images in touching position.

the cornea is symmetrical with reference to the plane of the arc. When the cornea is a surface of revolution, with its axis passing through the centre of the arc, this condition is fulfilled for all positions of the targets, but when the cornea is of a configuration approaching an ellipsoid of three unequal axes, the position of the arc

Fig. 517.—Overlapping of Double Images — As = 2 D.

must be such that its plane shall bisect the ellipsoid in one or the other of its two principal planes. In all other positions of the arc the images of the four targets appear more or less distorted, and the images of the two pairs of targets are not in the same line—see Fig. 518.*

This distortion and oblique displacement of the two images, in all but two positions of the arc, reveals at a glance the presence of corneal astigmatism. To find the meridian of greatest corneal curvature, the arc is turned until the images are seen in a line and most widely separated.* The two targets are then moved inward or outward on the arc, until the images are brought into the position of contact. Lastly, the arc is turned through an angle of 90°, or until the images are again seen in a line, and the number of overlapping steps, which represents the number of dioptries of corneal astigmatism, is

Fig. 518.—Double Images not on a Level.—Astigmatism Present.—Arc not in a Principal Meridian.

noted. The examination of the two eyes need not consume more than two or three minutes.

The measurements of corneal astigmatism as made with the ophthalmometer agree remarkably, in most cases, with the results obtained by the use of methods which show the total astigmatism of the eye. The agreement in the direction of the principal meridians is especially close, so that in by far the greater number of cases the direction of the axis of the correcting cylindrical glass may be taken directly from the reading of the instrument. In respect to the grade of astigmatism the agreement is less exact, for the reason that the observed corneal astigmatism is often modified by an astigmatism attributable to an oblique position of the crystalline lens. As a rule, the meridian of greatest corneal curvature is approximately vertical, and the meridian of greatest lenticular refraction is approximately horizontal; the total astigmatism is therefore generally somewhat less than the corneal astigmatism when the meridian of greatest corneal curvature is approximately vertical, and greater when, contrary to the rule, it is approximately horizontal.

In a comparatively small number of instances the total astigmatism is found to vary very widely from the cor-

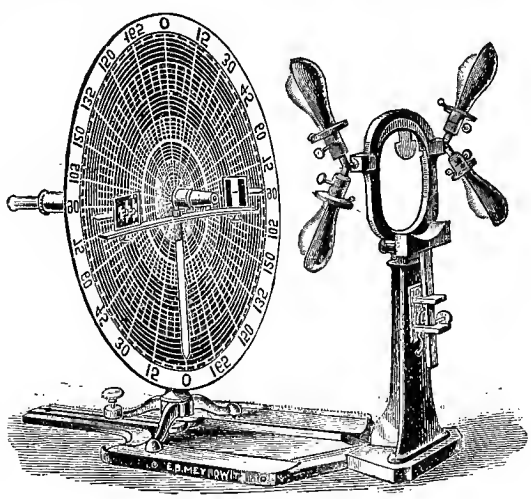

Fig. 519.

neal. For example, a relatively high grade of lenticular astigmatism may so far dominate a corneal astigmatism as largely to control both the direction of the principal meridians and the grade of the total astigmatism. Again,

* For an analysis of the phenomenon of distortion of the image formed by a mirror of asymmetrical curvature, also of the same phenomenon as it occurs in the case of a lens of asymmetrical refraction, see a paper by the writer: Ein Beitrag zur Theorie der Cylinderlinsen: Graefe's Archiv, 1887.

* By interchanging the targets the images may be brought into the position of contact when the arc is set in the meridian of least corneal curvature, and the overlapping steps counted in the second position of the arc; in practice this is found to be more convenient, for the reason that the meridian of least curvature is, as a rule, approximately horizontal, and it is easier to adjust the targets in the horizontal and to observe the overlapping of the images in the vertical meridian.

it is not uncommon to find a low grade of astigmatism, oftenest with the meridian of greatest refraction horizontal or nearly horizontal, in the absence of corneal asymmetry. Lastly, the ophthalmometer occasionally reveals an anomalous condition in which the corneal meridians of greatest and least curvatures are not at right angles to each other.

Not only has the Javal-Schiötz ophthalmometer greatly advanced our knowledge of astigmatism but it affords, also, most important special information in every case of investigation of the refraction of the eye.

The instrument-maker Kagenaar (Utrecht, 1887)[11] has somewhat cheapened the original Javal-Schiötz ophthalmometer by substituting a pair of weak glass prisms, turned in opposite directions, for the doubly refracting prism of Iceland spar. Leroy and Dubois (1888)[12] have also produced a low-priced ophthalmometer, in which the doubling of the image is effected by means of two plates of thick glass as used by Helmholtz. Javal has lately (1889)[13] brought out a new model—see Fig. 519—in which the shape of the targets has been somewhat altered; and the direction of the meridians of greatest and least corneal curvature is read on the reflected image of the large disk which now constitutes the most conspicuous feature of the instrument. *Carl Koller.*

OREXIN. (Phenyl-di-hydro-quinazoline hydrochloride). This name, derived from the Greek word signifying appetite, is applied to a derivative of quinoline, its chemical formula being C_6H_4 NCH CH_2N C_6H_5 HCl + $2H_2O$. It originally was produced in bright, colorless, lanceolate crystals, without odor, containing two molecules of water, which effloresce on exposure. More recently it has been supplied as a grayish powder. It has a bitter, pungent, and almost caustic taste, it irritates the mucous membrane of the nose, and at times causes a burning sensation in the throat and œsophagus. It is freely soluble in hot water.

Chloride of orexin was introduced by Professor Penzoldt, of Erlangen (*Therap. Monat.*, February, 1890), as a stomachic of decided value, as it was found to exert a tonic influence over the digestive organs, and a stimulant action on the appetite. It possesses neither antipyretic nor antiseptic properties. Penzoldt used it in a great number of cases in anorexia in healthy individuals, as well as in others suffering from various diseases accompanied by loss of appetite. Its use is contra-indicated when there is gastralgia, acute catarrh, ulcers, or any condition in which there is hyper-sensibility of the mucous lining of the stomach, on account of its local irritant action. It was found that the secretion of hydrochloric acid was increased, and that food was digested in from half to three-quarters of an hour sooner when orexin was given than under ordinary circumstances. The increase in the appetite occurred in some cases after the first few doses, in others the treatment had to be continued for several days before its effects began to show themselves. The class of cases in which it proved most serviceable were those in which the stomach was not diseased, but where the loss of appetite was due to some general condition, such as anæmia, phthisis, or debility. It was of special value in commencing pulmonary tuberculosis, its employment being followed by a considerable increase in body-weight. The dose is from three to seven grains, once or twice a day. It was at first used in the form of a pill, prepared as follows: hydrochloride of orexin, two grammes; extract of gentian, q. s.; powdered marshmallow, q. s.; to be made into twenty pills. From three to five to be taken daily. Subsequently it was found that the pills were not as effective as the powder given in wafers, on account of its insolubility, and when gelatine coating was added they were still more insoluble and inactive. Penzoldt now recommends that wafers are to be preferred. It is advised to give a cup of beef-tea, broth, or cocoa with each dose, on account of the pungent properties of the remedy.

Since its introduction many conflicting statements have been made, and there is a great deal of uncertainty regarding its action. The failures were undoubtedly in many instances due to an inferior quality of the drug, and in others to the mode of administration. Not a few practitioners have obtained the same satisfactory results as those indicated by Penzoldt, and the drug certainly appears to exert a favorable action in certain cases, but its employment is restricted to a limited class of cases, and is liable to cause great irritation where the local condition is such as to require sedative remedies, instead of stimulation.

According to Egasse, one-twelfth to one-third of a grain, given to frogs, paralyzes the motor nerves of peripheral origin. In rabbits, three-quarters of a grain for each two and a half pounds of body-weight, produces no toxic symptoms; in doses of four grains it causes toxic phenomena, trembling, spasms, enfeebling of the respiration and of the cardiac muscle. The blood becomes dark-colored, the blood corpuscles are diminished in size, and methæmoglobin is produced. *Beaumont Small.*

OREZZA. A spa in Corsica, the chalybeate waters of which are largely exported.

LOCATION.—Orezza is picturesquely situated in the interior of the beautiful island of Corsica. It is about two thousand feet above the level of the sea, and is, therefore, cool enough to merit its reputation as a summer resort. The climate is said to be equable and invigorating. The little village is not easy of access, and is, therefore, never crowded.

ANALYSIS. — The cold ferruginous waters of Orezza bubble up through several springs. One thousand grammes contain, according to Poggiale:

	Gramme.
Carbonate of lime	0.602
Carbonate of magnesia	0.074
Carbonate and oxide of iron	0.128
Sulphate of lime	0.021
Chloride of potassium / Chloride of sodium	0.014
Silicic acid	0.004
Alumina	0.006
Traces of carbonate of lithia, of oxide of manganese and cobalt, and of arsenic acid	0.849

The water is palatable, owing to its large proportion of free carbonic-acid gas.

INDICATIONS.—Although often employed as a mere table-water, the Orezza springs are useful in anæmia, chlorosis, atonic conditions of the organs of digestion, certain diseases of women, and in all morbid states where a mild iron tonic is indicated.

ACCOMMODATION.—Although there is a thermal establishment and so-called hotels, everything is on a primitive scale at Orezza. *Edmund C. Wendt.*

ORTHIN. Is one of the numerous compounds introduced for its antipyretic properties. It is a combination of hydrazin and para-oxybenzoic acid; the base is an unstable body, but the hydrochlorate is a stable preparation, and is the salt supplied under the name of orthin. It is very soluble in water. The solution should always be freshly prepared and preserved from the light. It is recommended as an antipyretic in typhoid fever, pneumonia, rheumatism, and all febrile disorders. Robert, who introduced it into therapeutics, claimed that it was non-toxic and free from all ill effects. Its use, however, has been accompanied by sweating, prostration, and

other symptoms of poisoning. In some cases small doses produced remarkable oscillations in the temperature. The dose advised by Robert is from five to eight grains. Very large quantities have been given to dogs without producing a fatal result, and thirty grains were given by mistake to two patients ; in both cases vomiting and other toxic symptoms occurred, but no bad results followed. On the other hand, one and a half grain has given rise to dizziness, cold sweating, and nausea.

Beaumont Small.

ORTHO-OXYETHYLANAMONO-ACETYL-AMIDO-QUINOLINE. This is the chemical name of Analgen, one of the most recent analgesics. It is reported that its synthetic composition was thought out before any actual formation of the compound was attempted, the aim being to produce a substance of high physiological power by combining with quinoline definite groups of molecules having a known acute pyretic action. Its mode of preparation has not been made public.

Analgen is a white crystalline powder, in the form of delicate needles. It is almost insoluble in water, but soluble in hot water, alcohol, and dilute acids. It is recommended for its valuable analgesic, antipyretic, and anti-rheumatic properties in doses of fifteen grains. It, however, must be administered with caution, as its therapeutic action is not, as yet, very thoroughly known.

Beaumont Small.

OSPEDALETTI. A new health-resort on the Riviera, midway between Bordighera and San Remo. Ospedaletti is a very small place, fronting the Mediterranean Sea. Great hopes were at one time entertained of its speedy transformation into a fashionable resort. But while nothing came of these expectations, Ospedaletti nevertheless has climatic advantages inferior to those of no place on the Riviera ; and the very fact of its extreme quietude will recommend it for a sojourn to some patients, to whom noise and crowds are intolerable. In the *Medical Record*, September 10, 1892, the writer mentions this little-known Riviera station about as follows :

Apart from the huge white Casino, the commodious new *Hotel de la Reine* (under Swiss management), a few minor pensions, several villas, and the rather dirty old village, constitute all there is to Ospedaletti. For undergoing a course of absolute quiet and repose in a sunny, well-protected situation, no more suitable place has yet come to my notice on the Riviera. American physicians could do worse than recommend it, where that line of treatment promises well for their patients.

Although most Riviera books only vaguely intimate it, there is no doubt that little Ospedaletti is more effectually protected from winds than almost any other resort on this coast. Moreover, it gets the sun early and keeps it late. There is also less blinding calcareous dust there than, for example, at Hyères, Cannes, or Nice.

Ospedaletti spreads out for something like a mile along the head of a small crescentic bay. The eastern headland of this bay is formed by Cape Nero, and the western extremity, much farther from the village than the former, by Cape Sant' Ampeglio. Thickly planted olive-hills surround the place, relieved in the plain by orange and lemon trees, and the usual array of graceful palms. Successive girdles of mountains protect it from the icy northern blasts, but less in a northeasterly than in a northwesterly direction. It is fully exposed only to the warm westerly marine breezes.

Immediately behind the village there rises a hill of gentle slope, and a number of mountain torrents of mild proportions trace their undulating course seaward. The place is so hedged in as to constitute a veritable sun-trap. There is little prospect of its ever being transformed into a town of any size. To some people this will seem an advantage rather than a drawback.

It is a pity that the railroad tracks are laid down close to the sea, as the beach is a sandy one, and a pleasant promenade along the shore has thus been practically ruined. As at Bordighera, the evening chill is less sudden and less intense than at resorts backed by bare rocks.

The drinking-water used at Ospedaletti is soft, sparkling, and pure. It is taken from the same mountain source as that which supplies San Remo, *i.e.*, Argallo. It could not be better, and is by long odds the best potable water to be found on the Riviera.

If the French speculators, instead of erecting a huge Casino, had utilized the hot sulphur springs found a few steps beyond the village, the permanent nucleus of an attractive sanitarium might easily have been established. As it is, this means of adding to the natural advantages of the place has been overlooked or neglected. Gouty and rheumatic elderly people should do particularly well at Ospedaletti, and a thermal establishment of modern type would soon be welcomed by discerning invalids belonging to that large class.

The fine natural situation of Ospedaletti, its pleasant surroundings, its proximity to the city of San Remo, its very solitude and smallness, in the opinion of the writer, entitle the place to a special and assured position among the health-resorts of the Riviera. *Edmund C. Wendt.*

OSTEND. One of the most fashionable and celebrated seaside-resorts in Europe. Ostend is situated in West Flanders, Belgium, about seventy miles from Brussels. It faces the North Sea. The season lasts from June to October, and the place is generally crowded by an international throng of visitors, who go there for noisy pleasure, or the vaunted benefits of surf-baths and bracing sea-air. The facilities for bathing are indeed excellent, and the beach is a remarkably fine sandy expanse. The place is expensive. It is doubtful if real invalids are much benefited there. But those needing "distraction" as a medicine, will not regret a season spent at Ostend, where every variety of seaside and other amusement is provided, and where the hotel accommodation is ample and of the best quality. During bathing hours the beach presents a scene of rare animation. The tide rises about fifteen feet in the harbor. There is a beautiful Kursaal, Casino, etc. Gambling is tolerated at most of the public and private establishments. There are a number of quiet seaside places near Ostend, such as Blankenbergh and Heyst. *Edmund C. Wendt.*

OUABAIN. A vegetable poisonous principle used by the natives of East Africa for the purpose of making their arrows dangerous and fatal. The exact source has not been determined, but it is obtained from the root of a shrub closely allied to *Carissa shimperi*, belonging to the order Apocynaceæ. Its action is very similar to that of Strophanthus, which is another member of the same order.

Ouabain is a glucoside, with the chemical formula $C_{30}H_{46}O_{12} + 7\ H_2O$, and appears to be a lower monologue of Strophanthin, the formula of which is $C_{31}H_{48}O_{12}$. It forms in rectangular crystals, which are white, transparent, colorless, and, to a very slight degree, bitter to the taste. It dissolves with difficulty in cold, but is very soluble in hot water. It is insoluble in chloroform, ether, and absolute alcohol. The best solvent is alcohol slightly concentrated. The part used by the Africans is the dried juice.

It is an extremely powerful poison, five to ten milligrammes producing death in animals in a very short time. It is estimated that one sixty-fifth of a grain introduced into the blood of man would prove fatal. It at first causes a severe cramp and convulsive movements. This is followed by prostration, great difficulty in breathing, retching, and vomiting, involuntary defecation and ultimately paralysis and death.

The local application of ouabain produces a condition of anæsthesia, and it has been found that a few drops of a 1 to 1,000 solution, instilled into the eye, causes an insensibility of the conjunctiva and cornea. This lasts for one or two hours, the pupil at the same time being powerfully contracted, and the tension of the eye increased. Some observers have failed to obtain this effect, and occasionally it has produced pain and irritation.

Therapeutically, ouabain has been employed as an antispasmodic in whooping-cough, by Dr. William Gem-

mell, of Glasgow (*British Medical Journal*, April 26, 1890). He reports the treatment of forty-nine cases, of which twenty-five had been dismissed cured, four had died, and the remainder were under treatment. The fatal terminations were due to diphtheria, meningitis, and progressive emaciation. From his observations, he arrives at the following general conclusions: 1. Ouabain is of marked benefit during all stages of whooping-cough, and if carefully used, produces gratifying results. In the first stage it cuts short the attack; in the second, it reduces the violence and frequency of the cough, and diminishes the number of whoops; and in the third, it hastens convalescence in a remarkable manner. 2. Ouabain is a drug which does not appear to be cumulative; its administration can be stopped suddenly without any ill effect beyond an exacerbation of the whooping-cough; it can be as suddenly resumed. 3. It should be given, at first, at any rate, in a dose of $\frac{1}{100}$ grain every three hours ($\frac{1}{125}$ grain daily). 4. For children under one year of age, the dose should not exceed $\frac{1}{200}$ grain every three hours. 5. In children of from six to twelve years of age, if the cough be very violent, and the whoops are numerous, $\frac{1}{50}$ grain may be given in each dose, but the action of the drug must be carefully watched. 6. Ouabain may be given alone, dissolved in water, or in combination with potassium bromide, or chloral hydrate. The simplest way is to dissolve one grain in distilled water, so that each minim of the solution shall be equal to $\frac{1}{100}$ grain ouabain, as: ℞. Sol. ouabain, ℥. 48; syr. aurantii, ʒ iv.; aq. ad., ℥ vi. M. Sig. A teaspoonful every three hours. 7. Under the administration of ouabain, it is found that the temperature, pulse, and respiration are, in uncomplicated cases, slightly below normal. When the drug is pushed, the respirations become very slow indeed; in one patient, aged four, they were often as low as sixteen per minute. It is from this that danger is to be expected. During the administration the action of the skin is promoted, the amount of urine is increased, and the movements of the bowels become more regular. Ouabain has also been used with equally satisfactory results by Dr. J. Lindsay Porteous, of Yonkers, N. Y. (*New York Medical Journal*, vol. liv., 345). He gave it in three cases, one adult and two children, and in all marked improvement was immediately noticed. To a child of fifteen months $\frac{1}{400}$ grain was given every three hours; to a child of four years, $\frac{1}{200}$ grain every four hours, and to the adult, $\frac{1}{50}$ grain every three hours. In all these cases the patient was entirely well at the end of a week.

The physiological action of this drug has been studied by Messrs. Gley and Rondeau, and by Dr. Joseph Sailer (*Therapeutic Gazette*, November, 1891). These observers differ in some points: the former considered that the drug acted on the central nervous system and produced a condition of asphyxia; the latter entertains a different view and considers that it acts on the peripheral nerves and produces death by paralysis of the heart.

The following are the conclusions of Dr. Sailer regarding its action on the nervous system and circulation: —1. It diminishes and finally abolishes reflex action by paralysis of the peripheral sensory nerves, and this paralysis then extends to the sensory nerve-trunks. 2. It paralyzes the striated muscles by direct action upon their tissue. 3. It paralyzes the motor nerves only when the action in the body is very prolonged, or when a strong solution is applied directly to the nerve. 4. There does not appear to be any action upon the central nervous system. Upon the circulation it produces, at first, a slowing of the pulse due to a stimulating action upon the cardio-inhibitory function, and perhaps partly to a direct action upon the heart-muscle. At the same time there is a primary vaso-motor spasm, due to an action, either upon the vaso-constrictor fibres or upon the muscular coats of the vessels. The slowing of the heart may be so marked as to overcome the vaso-motor spasm and cause a fall of pressure. Then there is a sudden and great increase in the pulse-rate, caused by depression and final paralysis of the vagi, and, at the same time, increase in pressure, due partly to increased heart action, and partly to continued stimulation of the vaso-motor system. At last the heart-muscle is paralyzed, and in a few seconds the pressure also falls to zero. *Beaumont Small.*

OXYGEN. Although oxygen is now being employed in the treatment of a great variety of diseases, it is only in conditions of asphyxia that it is used with any certainty of success. Where there is an excess of carbon dioxide in the blood, and a deficiency of oxygen, a few inhalations afford an almost instant relief, whether it is due to pneumonia, croup, diphtheria, phthisis, and many other diseases, or in poisoning by coal-gas, opium, diabetes, etc. Pneumonia is one of the most important diseases in which it can be utilized, and during the past few years in the great number of cases reported it has proved of very general benefit. It is not used as a remedy, but as a means of relief when the lungs are unable to carry on their function and the character of the blood is changed. Its use is indicated when there is shallow and labored breathing, commencing lividity of the ears, lips, and fingers, and other well-known signs of deficient aëration and commencing cyanosis, in which the vital powers are depressed and the system no longer responds to ordinary remedies. It is here that the inhalation of oxygen acts as no other medicine can; it renders the blood pure and arterial, and exerts a stimulating action on the heart and lungs, the expression becomes brighter, the skin changes to a more healthy hue, the cardiac force increases, and the dyspnœa is eased. Although all have not derived the same benefit, those who have been successful are loud in their praises of its usefulness, its ease of application, and its freedom from ill-effects. In many cases the condition of cyanosis returns when the inhalations are discontinued, and it becomes necessary to repeat the treatment at short intervals. At times life has been maintained for days until the morbid process ceased and the lungs regained their normal condition.

From one to two gallons of the gas is an ordinary dose, which may be administered once or twice a day, as occasion requires. In emergencies, when an immediate and effective action is required, there is no limit to the dose, and in some severe cases where a continuous action was required, enormous quantities have been used. In one case reported, nearly two hundred gallons were inhaled in the twenty-four hours. A moderate, and generally an efficient dosage, when its frequent use is required, is from half to one gallon every twenty minutes. The administration of the gas is usually managed with the aid of a tube and mask, which fits over the mouth and nostrils. The inhalation should be slow and as deep as the condition of the patient will allow. The rubber balloons afford an easy method of supplying the gas; it being heavier than air a very slight elevation will facilitate the flow, and this may be aided by gentle pressure. When the compressed gas is used it must be more cautiously managed, that the force be not too great nor conveyed too directly into the lungs. It may be found an advantage to fill the balloon with the quantity required for the dose, instead of using it directly from the reservoir. When an immediate action is not required it is recommended that the gas be conveyed by one nostril only, the other being free to inhale a supply of air to dilute the pure oxygen. In cases of insensibility, or when the respiration is feeble, it becomes necessary to assist by means of artificial respiration, and in some instances tracheotomy has been performed and the gas forcibly introduced into the lungs.

Formerly an obstacle to its employment was the difficulty with which it was obtained and the frequent contamination with irritating compounds of chlorine and nitrogen. This difficulty is now overcome, as it is plentifully supplied in all large centres, and its application is as simple as any form of inhalation. When the gas is not easily obtained, or when large quantities are required, its preparation must be considered. Oxygen is a gas that is readily obtained, and many methods of preparing a pure supply are devised. Some may be easily followed, but the others are complicated and dangerous, or expensive. The following has been suggested as a process that may be conducted by anyone, and one that produces a free supply of pure gas: A porcelain tube of

about twenty centimetres long and having an inside diameter of twenty millimetres, is filled with twenty or thirty grammes of baryta or barium monoxide in fragments of about the size of small nuts. This is gently warmed, and the air passing through the tube is deprived of its oxygen, and barium dioxide is formed. If one end of the tube is closed and the other carried to the mouth of a receiver, by way of a pneumatic trough, and heat applied to a low redness, pure oxygen is given off and easily collected. Barium dioxide yields about one-tenth of its weight of oxygen, and from ten grammes one gramme of oxygen is obtained, which measures about one litre.

Pure oxygen may also be readily and simply obtained by the decomposition of hydrogen peroxide (*q. v.*).

Other means of conveying the oxygen to the blood than through the lungs have been found efficacious. Dr. Francisco Valenzuela, physician to the Provincial Hospital, Madrid, administered it per rectum, in order to obtain a greater absorbing surface than might be possible in many cases of lung disease. He adopted this method in many cases and found the dyspnœa and other symptoms relieved in a remarkable manner. The gas was rapidly absorbed and carried by the portal vessels very directly to the lung tissue. It appeared to be as readily taken up as by the lungs, four injections of five litres each being absorbed in an hour. It has also been used by being introduced into the stomach, partly for its action on the system, as well as for its local effect on the walls of the organ. It is preceded by *lavage*, and the gas is then conveyed by means of an œsophageal tube. The patient is made to eructate the gas, and the process repeated two or three times.

The use of oxygen has been extended to numerous other diseases in which there is no interference with respiration, but only a depraved condition of the system in which the vital processes are carried on in a slow and feeble manner, as in anæmia, chlorosis, etc. It is a question, however, how far the inhalation of oxygen will benefit such affections. It is evident that the amount that can be absorbed is only such as the hæmoglobin present in the blood is capable of receiving. Physiology also teaches us that only a very small proportion of the oxygen in the air inspired is absorbed, so there cannot be any great deficiency in the supply. It must not be forgotten, however, that the presence of an increased supply of oxygen stimulates the reflex mechanism of the heart and lungs, and this may account for the beneficial effects that are often found to follow its use in such cases.

In gastric disorders, accompanied by a catarrhal condition of the mucous membrane, with anorexia and vomiting, it may be introduced directly into the stomach, or compressed in water and administered as oxygenated water. Its action in such conditions is said to give relief, but its use is not very general. In lithiasis it has been used as an enema, with the idea of aiding the conversion of uric acid into urea. It is found to produce a beneficial action very rapidly by lessening the uncomfortable symptoms and improving the general condition of the patient. In all cases in which it is desired to favor metabolism this mode of administering may be adopted.

The use of oxygen is usually quite harmless in acute pulmonary diseases, but in chronic phthisis, accompanied by hæmoptysis and destruction of tissue, it must be used with caution. It is dangerous in advanced heart disease in which there is degeneration of the muscular tissue and dilatation, particularly if the heart is engorged with blood. It must also be given slowly and with caution when there is atheromatous disease or aneurism of the aorta. *Beaumont Small.*

OXYQUINASEPTOL (Diaphtherin). This is one of the latest antiseptics introduced, and its authors claim that it is the most powerful compound that has yet been prepared. It was reported upon by Professor R. Emmerich, of Munich, at the Eleventh Congress for Internal Medicine, held at Leipsic in 1892. Its mode of preparation has not been made known, but its composition consists of two molecules of oxyquinolin and one of aseptol. It is a definite chemical compound with the formula of $C_6H_4(HOC_9H_6NHO)_2SO_2$.

It forms in amber-yellow transparent hexagonal crystals, which, when powdered, are soluble in one part of water, also soluble in dilute alcohol, very sparingly soluble in absolute alcohol. It melts at 185° F. without decomposition, but is not altered chemically at 212° F. Bacteriological experiments show that it is much superior to carbolic acid, the preparations of cresol and other ordinary antiseptics. It is stated that a three-tenths per cent. solution will kill the staphylococcus pyogenes aureus in a quarter of an hour, while a one-half per cent. solution of other antiseptics had no effect whatever. A one-tenth per cent. solution was found sufficiently strong to kill Koch's cholera bacillus in ten minutes, and the bacillus of diphtheria and other pathogenic bacteria were destroyed by a one-fifth per cent. solution in the same space of time.

It is recommmended as an antiseptic dressing in surgical practice, and for the treatment of ulcers, wounds, etc. A solution of one-half to one per cent. is said to be sufficiently strong for a lotion or to saturate dressings. It is deprived of all irritating properties, and not only disinfects the part and maintains it in an aseptic condition, but also exerts a very decided curative action on the wound. Its toxic action is very mild. Professor Emmerich injected eight minims into hedgehogs without any noticeable disturbance manifesting itself. Locally, he used solutions as strong as fifty per cent. without any injurious effect.

The sole drawbacks are said to be a tendency to act on instruments, causing a black deposit, and a tendency to discolor the skin and clothing. *Beaumont Small.*

PAMBOTANO. A Mexican plant, *Calliandra Houstoni*, Benth., which has a local reputation as a remedy for malarial fevers, and has been suggested as a substitute for quinine. The members of the calliandra group form an order of leguminous plants which are found as far north as California and extend southward to Buenos Ayres. The leaves are all bi-pinnate, but vary much in size and number. The flowers are very bright and showy, the corollas are small and hidden by the very numerous large stamens, which are usually of a bright crimson color.

The root is the part employed. It has not been analyzed properly, but is known to contain a large percentage of tannin, and a glucoside has been separated by Bocquillon. The active principles are soluble in water and alcohol. In Mexico it has undoubtedly proved of much service in the treatment of intermittent fevers, and recently it has been used in France in malarial, typhoid, and other fevers as an antiperiodic and antipyretic with decided benefit. The decoction is the usual mode of preparing the remedy, the dose of which is from one to two and a half ounces. *Beaumont Small.*

PANARITIUM ANALGICUM. This rare affection of the nervous system is commonly called "Morvan's disease," from the name of the physician of Lannelis, in Brittany, who first described it in 1883. It is regarded by many observers as merely a special clinical type of syringo-myelia, to which it may be closely related in its pathology, and which it certainly resembles in many of its symptoms. Its most characteristic clinical feature, which gives it the name by which, in the present uncertainty as to its pathology, the disease should be called, is the occurrence of a succession of usually painless whitlows, commonly followed by more or less complete destruction of the terminal phalanges of the fingers (analgic panaritium.)

Symptoms.—The patient may first seek advice for the relief of neuralgic pains in one hand and forearm, less frequently in both, or in the upper and lower limb of the same side. At this time a correct diagnosis can hardly be expected, as there is nothing characteristic about the neuralgia. In some cases the initial pains are slight, or entirely absent. The case, then, first presents itself as one of whitlow, which is always severe and deep-seated. The first whitlow may be painful, but the later ones,

which appear at intervals, perhaps of weeks, and often of years, are entirely painless. It is this peculiarity which is most striking, and which first attracted Morvan's attention.

A further examination shows that whitlows are only the most noticeable of a series of trophic disturbances in the affected limb. The hand and forearm are atrophied, often to a marked degree. Deep-seated ulceration has been found in the hand, and abscess in the forearm, without any known injury, and presumably of trophic origin. The skin of the hands and the nails are cracked and fissured.

The changes in sensibility are, next to the whitlows, the most striking phenomenon, and are of especial interest in connection with the differentiation of the disease from syringo-myelia. In fully developed cases all forms of sensation have disappeared—contact, pressure, heat, cold, and pain, are all unfelt. The loss of sensation extends often beyond the apparent atrophy. It may include the whole arm, and at times the adjacent parts of trunk and neck, and even the face.

There is marked weakness of the affected limbs. The electrical reactions gradually disappear as the disease advances. The reflexes remain unchanged, or, as has been observed in the lower extremities, are somewhat increased. Vaso-motor disturbances are usually marked, the hand and forearm being livid or pale, and feeling cold to the touch.

The joints are not affected as a rule, though lesions of the wrist and shoulder, resembling those of tabes dorsalis, or dry arthritis, have been observed. Scoliosis occurs in a considerable number of cases, constituting another point of resemblance to syringo-myelia.

As the disease progresses the lesser peculiarities develop, such as the cracks in the skin and nails. The whitlows recur, and being always deep seated, result usually in complete destruction of the phalanges on which they are situated, so that in the course of time several fingers of each hand are shortened to one or two phalanges. The fingers become distorted by a contraction of the interossei muscles, so that they are fixed in an attitude of partial flexion. The longer the disease has lasted, the more likely are the lower extremities to be attacked by symptoms similar to those of the upper extremities, though less severe.

The great variety observed among the small number of cases yet reported makes precise and unqualified assertions as to symptoms impossible, especially in regard to the points of resemblance to syringo-myelia. The gradation of symptoms affords an unbroken series of clinical types, connecting the two diseases.

Pathology.—The disease has only been known for ten years; it is very rare, very slow in its progress, and involves little danger to life. Hence it is not surprising that our knowledge of its pathology is extremely limited. To consider first the undisputed points, the most obvious lesion is whitlows.

The term whitlow, or felon, is an unfortunately vague one, as generally used, but in this disease it is precise enough. The lesion is always a periostitis, followed by the necrosis of the affected phalanx and its ultimate exfoliation. The pathological changes in the skin appear to be nothing but the effects of impaired nutrition and have no especial character.

The peripheral nervous system is profoundly affected in the diseased limbs. The amputations which the progressive ulcerations and periostitis have in some cases required, have materially increased our opportunities for studying the pathology of the peripheral nerves; and these amputations, with what autopsies have been obtained, have established one pathological fact, which, it seems to the writer, may be regarded as the key to the nature of the disease. There is in all cases a marked degree of neuritis, great increase in the connective tissue, with degeneration or complete disappearance of the nerve-fibres themselves. These lesions are most intense at the peripheral ends of the nerves, and gradually diminish toward the nervous centres in a manner characteristic of an ascending neuritis.

Our knowledge of the changes in the cord is more limited, and affords much more conflicting evidence. The cord has been found, in at least one case, much less affected than the peripheral nerves. The posterior horns and posterior columns were the seat of a mild degree of diffuse sclerosis in the cervical region. The sclerosis included the vessels of the affected parts, and had resulted in more or less complete occlusion. There were no cavities in the cord. In other cases cavities have been found, as in syringo-myelia. In one the cavity extended about the whole length of the cervical and dorsal regions. The sclerosis of the posterior horns and posterior columns harmonizes with the disturbances of sensations observed in life.

This is really all that we certainly know of the pathology of panaritium analgicum. Yet it is enough to afford strong arguments to those who advocate the identity of the disease with syringo-myelia. However, the constant occurrence of peripheral neuritis, as the most severe lesion found, and the preponderance throughout the symptoms of the phenomena of trophic disturbances are facts of fundamental importance which cannot well be reconciled with the identity of the two diseases.

Differential Diagnosis.—A well-marked case of analgic panaritium can hardly be overlooked by any one who has the disease in mind while examining the patient. But it has already been remarked that there may be a great deviation from the characteristic type. The diseases to be considered are syringo-myelia, anæsthetic leprosy, two forms of scleroderma, symmetrical gangrene and tabes dorsalis.

In syringo-myelia the trophic changes are absent, except the atrophy of the muscles. The characteristic forms of sensation by which the sense of contact is preserved, while the senses of pain and temperature are lost, is one of the marked symptoms of syringo-myelia. It may exist in analgic panaritium, as the equal loss of all forms at the same period does not by any means always occur. But the separation of the different forms of sensibility, if marked and continued under prolonged observation, would be strongly against the diagnosis of Morvan's disease.

Anæsthetic leprosy is distinguished by the history of infection and the presence of characteristic lesions in other parts of the body. Moreover, the loss of digits is due to a true ulceration extending inward from the surface, and not to a periostitis. Such ulcerations can usually be traced to some slight abrasion of the skin or other injury.

Scleroderma, in the form known as sclerodactyla, leads to marked changes in the fingers, but the fingers are flexed in a characteristic manner, that is, only at the metacarpo-phalangeal joint, the other joints remaining nearly straight. The skin of the hands is glossy and adherent to the bone, and the same peculiarity occurs in the skin of the face, presenting the peculiar mask-like appearance characteristic of sclerodactyla.

Ainhum is so rare that it need be mentioned only for the sake of completeness. It is confined to tropical regions. It rarely attacks persons of European race, and the loss of the digits, more often of the toes than of the fingers, takes place by a process of constriction somewhat resembling the growth of a band of connective tissue and consequent gangrene.

Symmetrical gangrene, or Reynaud's disease, lacks the peculiar disturbance of sensation. The vaso-motor changes are much more profound, and are a source of much more discomfort to the patient. The ultimate gangrene, which results from the vaso-motor changes, does not really offer many points of resemblance to the periostitis of analgic panaritium. True deep-seated whitlows are at least very rare in symmetrical gangrene, and it may be doubted if they occur.

Tabes dorsalis is too well marked to need discussion, except to point out that the perforating ulcers which occur in it have little resemblance to whitlows, and that the Romberg symptom, the Argyle-Robertson pupil, the loss of knee-jerk, etc., are all lacking in Morvan's disease.

Etiology.—By far the greater number of cases have

been observed in Brittany; but reports of single observations come from other districts of France, and the disease has been seen in other countries of Europe and America. The locality of most of the cases in a fishing community, and the occupation of a large number of the patients necessitating the handling of fish, has led to a suggestion that the disease is a neuritis of infectious origin; which seems the most probable hypothesis in the present condition of our knowledge. The lesions in the cord, which are constant, are simply sclerotic, and these may be conceived as secondary to an ascending neuritis. In rare cases injuries have been reported as causes, but there are no cases in which any close connection has been made out between trauma and the occurrence of the disease. If the disease is really a form of syringo-myelia, or primarily a disease of the cord, congenital malformation might be considered as a probable explanation; but we must confess that our knowledge is too limited to afford any definite conclusion as to the origin of the disease. The disease occurs at all periods of life, from twelve years to old age, and is more common in men than in women. Unlike most nervous diseases, it is, as is obvious from what has been said, less common in great cities than in, at least, one country district.

PROGNOSIS.—The prognosis is at present necessarily unfavorable as to recovery, though there are few cases in which the patient has died from the disease. There are a sufficient number of characteristic cases which have very much improved, almost recovered, to afford a reasonable hope in any case where the ulceration or formation of whitlows is not so malignantly active as to compel repeated amputations. If the hypothesis of an infectious ascending neuritis, as the primary lesion, is correct, great hopes may be entertained of recovery, if the patient can be removed from exposure to the source of infection.

TREATMENT.—Little can be accomplished in the treatment of this disease. The hackneyed recommendation about general care of the health, tonics, and liberal nourishment may be repeated. The local treatment of the whitlows is of great importance, and early and free incision should, of course, be made, and the wound should be treated with every antiseptic precaution. Where there is any reason to suspect that we have under observation an early stage of this disease, the sources of infection to the hands should be closely inquired into, and thorough antiseptic washing of the parts, great care of all cracks and abrasions in the skin, should be advised. There is some reason to believe, from past experience, that cases in the early stage may be cured, at least for a time, by these measures. *Frederic Coggeshall.*

PANCREATIN. This is a mixture of various organic substances extracted from the fresh pancreas of some animal, usually the hog. It contains, with other things, four organic ferments or enzymes, and to these it owes its value. One of these has the power of converting albuminous substances into peptone, the second converts starch into sugar by hydrolysis, the third emulsifies fats, and the fourth, like rennet, curdles milk. The proteolytic or peptone-forming body bears the name of trypsin, the amylolytic, or sugar-producing one amylopsin, while the fat-emulsifier is called steapsin by some authors, and pialyn by others. The rennet-like body has not been named.

Trypsin digestion, while resembling that of pepsin in some particulars, is quite unlike it in others. The most marked difference is found in the fact that, whereas pepsin digestion can only be conducted in an acid medium, that of trypsin finds its most favorable condition in an alkaline one. In neutral, and even very feeble, acid solutions traces of its activity are revealed. This increases in degree with every increase of the quantity of sodium bicarbonate added until 1.2 per cent. has been reached, after which it again declines. At this point its maximum power is reached. Hydrochloric acid solutions as weak as 0.2 per cent. quickly destroy it. Therefore, to give pancreatin combined with pepsin and hope to get good results from each is a delusion. As soon as pepsin is fairly at work the trypsin is destroyed. Trypsin further differs from pepsin in that it digests more rapidly, causes no swelling up or transparency of fibrine, but eats away its surface slowly by a sort of corrosive action, produces as a first product alkali albumin, instead of syntonin, has greater power over elastin and some other difficultly digestible substances, and instead of stopping at the production of peptone, continues its activity until this substance is broken up into simpler bodies like tyrosine, leucine, asparaginic acid, etc.

Amylopsin is the diastatic body of pancreatin. It hydrolyzes starch, converting it into sugar. In this it distinctly resembles ptyalin from saliva, and the sugar-forming enzyme common to almost every tissue of the human body. It acts with much greater promptness than ptyalin or the other kindred ferments, and while they all produce malt sugar, it alone can, in the brief time allotted to digestion, change this into dextrose. The dextrin produced by both ptyalin and amylopsin differs from the dextrin of diastase in not reacting with iodine. Wet pancreatin is easily destroyed by heat, but if perfectly dry it can be raised to a temperature of 162° C. (323.6° F.) without seriously injuring the amylopsin. Above 100° C. (212° F.) its power is slightly impaired.

Steapsin, the fat-emulsifying and fat-splitting enzyme, has never been isolated in anything like a pure state. Its existence is therefore only inferred from the nature of its work. It is very sensitive to alcohol and all acids not of the fatty series. Small quantities of these quickly render it inert, hence the great difficulty of securing a first-class article. It is soluble in water, and in the absence of acids not fatty it can be taken up with glycerine. Dilute alkaline solutions of sodium carbonate with sodium bicarbonate form the best medium for its extraction yet devised. It readily decomposes any fat, releasing the glycerine and its acid.

Less is known of the rennet-like ferment than of any of the other three. It has never been isolated even imperfectly, and is only known by the power it possesses of coagulating casein.

The study of pancreatin, as found in the pancreas, was first earnestly begun by Valentin, in 1844, when he showed its diastatic action. Eleven years later, Bernard published the fact that he had succeeded in digesting egg albumin therewith. Near this time Kroger reported the isolation of the amylolytic ferment. In 1862 Danilewsky first isolated trypsin, and about ten years later Kühne purified it sufficiently to believe that he could, by ultimate analysis, determine its exact composition. His percentage results are as follows:

Carbon	47.22 to 48.09
Hydrogen	7.15 to 7.44
Nitrogen	12.59 to 13.41
Sulphur	1.73 to 1.86

The pancreatin of commerce is usually of doubtful quality. Many samples are innocent of all power as ferments, others, while fairly good as samples of one enzyme, are deplorably deficient in one or more of the others. This renders the analysis of them somewhat tedious. Each enzyme requires a separate test. The National Formulary has supplied a standard for the trypsin value of pancreatin by the amount of casein it can peptonize. The following is its method;

"If there be added to 4 fluidounces of tepid water, contained in a suitable flask or bottle, first, 5 grains of pancreatin and 20 grains of bicarbonate of sodium, and afterward one pint of fresh cow's milk previously heated to 38° C. (100.4° F.), and if this mixture be maintained at the same temperature for thirty minutes, the milk should be so completely peptonized that, on adding to a small portion of it, transferred to a test-tube, a slight excess of nitric acid, coagulation should not occur" (278).

In saying that coagulation should not occur, it slightly overstates the fact. However perfect the digestion may be, a slight coagulation can be observed, but it is not sufficient to hide the completion of the reaction or to render it doubtful. In peptonizing milk for the sick, pancreatin is almost exclusively used, hence the importance of the

National Formulary test and of the instructions given by that volume regarding the character of the product. It says: "Peptonized milk as prepared by the above process, or when the process is allowed to go on to the development of a very distinct bitter flavor, should not have an odor at all suggestive of rancidity. Milk has simply a marked bitter taste when thoroughly peptonized." When it is known that the bacteria of putrefaction are likely to exist in solutions of pancreatin that have been imperfectly prepared, or in the dried extract that happens to be hygroscopic in character, or made from a stale pancreas, the advantage of this warning is apparent. The process for making the standard pancreatin of the National Formulary is the following:

"Pancreas of the hog, fresh,
Water,
Alcohol.....each, a sufficient quantity.

"Reduce the fresh pancreas of the hog, freed as much as possible from fat and membranes, to a fine paste by means of a suitable chopping machine. Mix it with half its weight of cold water, and knead it thoroughly and frequently during one hour; then transfer the mass to a strainer, express it forcibly, filter the liquid as quickly as possible through flannel, and add to the filtrate an equal volume of alcohol. Collect the precipitate, drain it, and free it by pressure from as much of the adherent liquid as possible. Then spread it on shallow trays, dry it by exposure to warm air, at a temperature not exceeding 40° C. (104° F.), reduce it to powder, and keep it in well-stoppered bottles" (Formula 278). In working up large amounts of pancreas, especially during warm weather, septic changes are likely to occur before the task is completed, unless some means are taken to prevent the same. In such cases chloroform or thymol is usually added as a preservative agent, since they are found to possess but little inhibitory power on the action of the ferments.

The value of the amylopsin present in any given specimen of pancreatin is determined by ascertaining how much starch it can convert into sugar in five minutes at a temperature of 40° C (104° F.). One gramme of the pancreatin is digested for four or five hours in 100 c.c. of distilled water. Of a one per cent. solution of starch 10 c.c. are diluted to 100 c.c., and 1 c.c. of the pancreatin solution added. If in five minutes this is found free from starch by its failing to give a blue color to a very dilute solution of iodine, then a larger quantity of the starch solution is tried with the same amount of pancreatin. By continuing the increase the point can be found where the color first appears, and the amount of starch changed easily calculated. If the blue color is present on the first trial, then instead of taking 10 c.c. of the starch solution, 9, 8, 7, or some lower number of cubic centimetres can be tried, until the point is discovered where the blue color fails to appear.

"Pulvus Pancreaticus Compositus," the peptonizing powder of the National Formulary, is composed of five grains of pancreatin of standard strength triturated with 20 grains of bicarbonate of sodium. One such powder is to be added to 4 fluidounces of tepid water in a suitable flask. To this is next added one pint of fresh milk that has been warmed to 38° C. (104° F.). After standing at this temperature for half an hour the flask is removed to a cool place. It must not be used if kept over twenty-four hours, or if it has developed a distinctly unpleasant, bitter taste. *Robert G. Eccles.*

PAPAIN, PAPOID, PAPAYOTIN. These names are indiscriminately given to the active principle of the juice of *Carica papaya* Linn., the papaw tree of southern tropical countries. An attempt has been made to apply the term papain to the juice itself, and papayotin to the active principle obtained from the juice, the latter being four or five times stronger in its action. Originally these terms were used with a different meaning; papayotin was the name given by Peckolt, of Rio Janeiro, to the deposit that results from fermentation of the juice, and papain was given by Wurtz and Bouchet, who made known the peculiar properties of the plant in 1889, to the product that is precipitated from the juice by the addition of alcohol.

The trunk, the leaves, and the fruit of the tree contain an abundance of the milky juice, which is used by the natives to soften and make tender their meat-food. This effect is obtained by simply wrapping the meat in the larger leaves of the tree, or by rubbing the juice of the fruit or leaves over the surface.

Papain is a powerful vegetable ferment which possesses digestive properties resembling those of pepsine. It acts upon albuminoids, hydrating them and converting them ultimately into peptones. It also converts starch into maltose, and emulsifies fats. It is antiseptic in its action and prevents abnormal fermentation in the stomach and intestines. Its action is not checked by antiseptics, and papain may be administered with salol, carbolic acid, and even corrosive sublimate without its action being interfered with. It acts at all temperatures, but is most effectual when the temperature is slightly elevated. Some difference of opinion has arisen as to the effect of acids and alkalies on the ferment. It is generally stated that it acts equally well in alkaline, acid, and neutral solutions, but recent experiments indicate that its greatest activity is attained in the alkaline media. If the acidity is not marked and the quantity of ferment very great, the digestive process is continued, but in the normal degree of acidity of the stomach its action is at once checked. The ferment is not destroyed by the acid, as it continues to act if the acid is neutralized and the media rendered neutral or alkaline. Papain has no action whatever on living tissues, and may be given freely without producing any ill effect. It is frequently spoken of as a substitute for pepsine, but its chemical properties indicate that it is a very different substance, and could not be made to replace it under normal conditions. Experiments that have been made to determine the relative digestive powers of the two ferments are misleading, as papain is most active in alkaline solutions, while in acid solutions pepsine exerts a more powerful action.

Therapeutically, papain serves to replace pepsine in the conditions of the stomach in which pepsine is unable to act. When the secretions are normal and acid, the use of papain is of no service unless it be to continue, in the alkaline secretions of the intestines, the digestion of such albuminoids as have passed from the stomach unchanged. It is especially useful where there is indigestion due to deficient secretion of gastric juice, or an absence of hydrochloric acid. In such case the use of an alkaline solution of papain favors digestion both directly and indirectly; first, by disintegrating and digesting the food, and second, by its property of stimulating the secretion of the peptic glands, while the alkaline solution induces the secretion of a more acid gastric juice. It also acts beneficially by checking putrefactive changes. Under these circumstances a combination of papain, bicarbonate of soda, and nux vomica has proved most serviceable. Papain also exerts a beneficial action by dissolving and removing the accumulations of mucus that collect in the stomach, and this action is favored by following it with copious draughts of water. It is also said to exert a sedative action in persistent vomiting and in all conditions of irritability of the stomach. The following table of conditions in which this vegetable ferment is indicated is given by Dr. Frank Woodbury:

1. In actual or relative deficiency of the gastric juice, or its constituents.
   - (*a*) Diminished secretion of gastric juice as a whole.
     Apepsia.
     Anæmia and deficient blood-supply.
     Wasting diseases.
   - (*b*) Diminished proportion of pepsin.
     Atonic dyspepsia.
     Atrophy of gastric tubules.
   - (*c*) Diminution of hydrochloric acid.
     Achlorhydria.
     Carcinoma.

(*d*) Relative deficiency of gastric juice.
Over-feeding.

2. In gastric catarrh.
(*a*) Where there is tenacious mucus to be removed, thus enabling the food to come in contact with the mucous membrane.
(*b*) Where there is impaired digestion.

3. In excessive secretion of acid.
To prevent duodenal dyspepsia.

4. In gastralgia, irritable stomach, nausea, or vomiting.

5. In intestinal disorders.
(*a*) In constipation due to indigestion.
(*b*) In diarrhœa, as a sedative.
(*c*) In intestinal worms. This claim the writer has not personally verified, but as the intestinal mucus which shields the worms is removed by papoid, it is easily understood that their removal would naturally result after its administration).

6. In infectious disorders of the intestinal tract.
(*a*) Where there is abnormal fermentation; by its antiseptic action, which may be heightened by combination.
(*b*) Where there are foreign substances present its detergent effect may be utilized in cleaning out the *débris* from the intestinal contents by digestion.

7. In infantile indigestion; here papoid not only readily peptonizes cow's milk, but the resulting curds are also soft and floeculent, resembling those of breast milk.

The dose is one or two grains, but much larger amounts may be given without any injurious effects. It may be given in pill form, in solution, or in powder, but in the latter form it should always be enclosed in waxed paper, as it readily absorbs moisture and undergoes changes. In whatever manner it is prescribed, the preparation should always be freshly made, and the drug itself should not have been exposed to the air, or carelessly preserved. Bicarbonate of soda is generally added, either to the powder or the solution, and vegetable bitters, ipecacuanha, rhubarb, etc., may be also combined at the discretion of the prescriber.

It is also said to possess an anthelmintic action, but this property has not received much attention. In the West Indies the unripe fruit and the seeds are used for this purpose.

As a local application, its solvent properties are taken advantage of to remove the false membrane in diphtheria and croup. A five per cent. solution in water or glycerine, applied freely, every hour if the symptoms require urgency, or less often if the condition of the patient will permit, will rapidly clear the throat by removing the membrane and mucus. Its use should be preceded by a cleansing gargle, that the solution may come directly in contact with the membrane. The conditions that are present are those that are favorable for the action of the ferment. The media are neutral, the temperature suitable for its most energetic action, and no further dilution of the solution takes place. In addition to the benefit that follows the removal of the impediment to free respiration, the application also exerts a disinfectant action, removing all fetor and preventing the absorption of the products of the specific poison, or of suppuration. In urgent cases, when the applieation is made every hour, the membrane is generally removed within three or four hours, in other cases, when it is applied every three or four hours, the membrane is not destroyed for two or three days, but it is under control from the first application, and after three or four paintings its character is changed and it becomes thin and glairy. In some instances the powder itself has been applied, and in laryngeal or post-nasal diphtheria the powder may be blown through a glass tube, or a spray of the solution employed.

It has also been used locally for the removal of warts, corns, condylomata, and other blemishes from the skin. The following solution is recommended for this purpose: papain, twelve grains; borax, 1 drachm; water, two drachms. *Beaumont Small.*

PARIS, PARISETTE. An herbaceous perennial plant, *Paris quadrifolia* Linn., belonging to the order *Liliaceæ*. It is a native of Europe, and is closely allied to the *Trillium*, which is so common as an American wild flower. It sends up a single stem, bearing near its summit four whorled large, ovate, acute leaves, and a single terminal large green flower. The flower is distinguished by having six to ten spreading or reflexed sepals, anthers, with their cells fixed one on each side of an awl-shaped filament, and a three- to five-celled berry. Chemical analysis of the plant has obtained a glucoside *Paridin*, which is decomposed into paridol and glucose.

The study of this plant, as well as the allied trilliums, has recently been undertaken by Dr. F. Heim. He has obtained from the plant one or more alkaloids which are as yet undetermined. These may be obtained by exhausting the dried plant with boiling alcohol, to which a little oxalic acid has been added. The alcoholic extract is filtered and distilled, and the residue treated with warm water. After precipitating by neutral acetate of lead and filtering, there is obtained a liquid which contains the alkaloids, and a precipitate which contains the glucoside.

Dr. Heim experimented with an extract made from the leaves, rhizome, and fruit. It acts on the sensibility, the mobility, the respiration, and the heart, by its influence upon the medullary centres. The primary action is the production of a short period of excitation, which is followed by a diminution of sensibility and reflex action, and a slowing and weakening of the respiration and heart-beats. The final action is a depression of the excito-motor force and failure of vital power.

A further study of this plant and the trilliums is recommended on account of the resemblance of its action to that of aconite. The indications are that in our common flora there is to be found a succedaneum for aconitum napellus. *Beaumont Small.*

PATELLA, FRACTURE OF THE. INDICATIONS AND CONTRA INDICATIONS FOR OPERATIVE INTERFERENCE. A review of some reported cases of fracture of the patella, treated by immediate suturing of the fragments, in which extensive suppuration followed the operation, suggests certain pertinent inquiries. These relate, first, to the persistency with which quite a number of cases so operated upon developed infectious inflammatory complications; second, to the fact that in the majority of cases the primary points of infection took place in the intermuscular planes in the thigh, and not in the knee-joint itself, although the latter became involved secondarily; third, to the immunity of the thigh structures from infection when these were uninjured, even in cases in which direct infection of the joint itself occurred and suppuration of the latter followed; fourth, to the fact that when excessive traumatism and infection were both absent, remarkably rapid healing took place; fifth, to the perfectly undisturbed course which cases pursued when the operation of wiring the fragments was performed as a secondary procedure, as compared with the primary operation.

In addition, attention has been called to the fact that in cases in which very slight or no distention whatever has occurred following the injury, as well as in those in which, effusion having taken place, the application of a firm bandage resulted in its prompt disappearance, the primary operation was followed by rapid and decided infection with resulting abscess of the thigh. On the other hand, the immunity from septic complications is to be noted in those cases in which no amount of bandaging that could be borne by the patient sufficed to prevent the occurrence of effusion within the joint cavity, or led to its removal or diminution if applied after it had taken place.

An interpretation of these facts, based upon the anatomical peculiarities of the knee-joint, as well as the observations of Riedel, of Jena, have led to some modification of the views of those who have heretofore advocated immediate arthrotomy and suture of the fragments. It cannot be doubted that very positive contra-indications may exist to the operation as a primary procedure, and

that these are found to relate principally to the occurrence of a rupture of the joint capsule, especially at the upper limit or that portion which lies beneath the vastus medius or rectus femoris muscle.

A glance at the anatomy of the knee-joint will readily suggest the case with which the first mentioned of these may enter as a most important factor in any given case. In the cavity of the knee-joint is found the largest synovial sac in the body. It follows the capsular investment of the joint, which is formed anteriorly by the quadriceps extensor tendon, the ligamentum patellæ, and the patella itself. For some distance above the articular line of the expanded condyles of the femur it forms a cul-de-sac, which passes upward beneath the quadriceps extensor tendon in front of the femur. In some instances a bursa communicating with the synovial sac prolongs the latter for some distance farther. This bursa is interposed between the tendon and the bone and communicates directly with the cavity of the joint.

The vastus internus and crureus, constituting as they do practically but one muscle, make up the lesser portion of the great quadriceps extensor. It arises from nearly the entire length of the internal, anterior, and external surfaces of the shaft of the femur; its attachment above is limited by its aponeurotic connection with the lower portion of the line which extends from the inner side of the neck of the femur to the linea aspera. It is also attached to the entire length of the latter at its inner side. A transverse partition is formed by this muscular plane between the anterior and posterior structures of the thigh for at least three-fourths of that portion of the femur which lies below the level of the hip-joint. The lower fourth of the anterior surface of the femur is separated from the crureus portion of the vastus internus by the intervention of the synovial membrane of the knee-joint. Thus it will be seen that the cavity of the knee-joint extends in an upward direction upon the anterior surface of the femur for at least one-fourth of the entire length of the latter, there terminating upon the plane of the attachment of the vastus internus. In case, therefore, of a rupture of this upper recess of the cavity of the knee-joint there would necessarily occur the passage of serum and blood from the latter. This would pour out upon the muscular plane above referred to, passing thence upward, and if sufficient in quantity, or forced out from the cavity of the knee-joint by the application of a bandage, it would find its way along this muscular partition until arrested by the aponeurotic attachment at its upper limit.

The occurrence of the unfortunate results of opening the knee-joint immediately following a fracture of the patella finds a reasonable explanation in cases in which every provision against septic infection had been taken and yet extensive suppuration, commencing in the structures in the thigh, took place, when it is borne in mind that the same force which produces the injury to the bone, *i.e.*, the sudden and violent contraction of the powerful extensor muscle, may, and in all probability does, inflict the further injury of tearing the reflection of the synovial sac lying between the muscle and the bone. After the patella gives way, the continuance of the same force as that which fractured it will, if continued, tear the joint capsule, and in a certain proportion of cases the latter will give way beneath the muscle itself, rather than upon the sides of the patella, where it is reinforced by the aponeurotic fibres from the lateral portions of the muscle.

It is not difficult to understand, in the light of these facts, that, in spite of every precaution, the opening of the knee-joint in these cases will render the patient liable to septic complications of a serious nature. It becomes almost impossible to accomplish disinfection along the route taken by the effused fluids that have escaped from the joint cavity. On the other hand, infection will occur with the greatest facility and will reach portions of the thigh practically inaccessible to the operator from the cavity of the knee-joint. The route of infection, in these cases, extends along the plane of the vastus externus muscle, between the latter and the anterior surface of the femur. The application of dressings and the bandaging will only tend, after the operation, to further the extension of the infection by forcing the effused fluids from the joint cavity through the rent in the upper recess.

The researches of Riedel * are very interesting in this connection. This observer, in a series of experiments, endeavored to demonstrate the resistance which the capsule of the knee-joint would bear to hydrostatic pressure. With the limb in the extended position, in the cadavera of strong males, 200 c.c. of fluid under a pressure of 3.5 to 4 metres produced rupture of the upper recess of the joint capsule. In this connection it may be said, however, that much less pressure may be sufficient to produce this effect in the living individual. It is a well-known fact that when rigor mortis is well marked an additional support is furnished to this portion of the knee-joint by the rigid muscular structures. It is more than likely, however, that the rupture takes place by direct tearing force rather than by increased pressure within the joint cavity.

Two cases are reported by Riedel in which opportunity was given for demonstrating the existence of rupture of the upper recess of the cavity of the knee-joint. One was a case of fracture of the patella, the patient dying upon the table during an attempt at immediate suturing of the fragments. An examination revealed the existence of rupture of the upper recess of the joint. In a second case, that of injury to the knee from direct violence, the effused fluid, mainly blood, found its way from the seat of the original injury and infiltrated itself along the muscular plane above described.

A larger amount of extravasation and consequent swelling need not necessarily occur in these cases of rupture of the upper recess. In fact, the surgeon's attention would scarcely be attracted by any change in the thigh itself. A condition, however, which should never fail to attract attention and arouse suspicion is the occurrence of but slight swelling and distention of the joint capsule, or, this having taken place, the fact that it has rapidly disappeared. On the other hand, increase of pain and tension produced by the application of a bandage would indicate that the joint cavity is still intact.

The extravasated fluids may find their way into the popliteal space in exceptional instances. From the fact, however, that the vasti have their origin high up, and that more space is present here for the extravasated fluid to find its way into than in the compact structures below and posteriorly, the former will find its way in an upward and anterior direction by preference. Discoloration of the skin, due to the hemorrhage and extravasation, will first make its appearance upon the inner aspect of the thigh, later on appearing at the outer side: in the course of time the infective process may find its way down into the leg.

A convincing proof of the occurence of rupture of the upper recess of the synovial cavity, in connection with severe injuries to the knee-joint and the readiness with which the effused fluid may find its way beyond the limits of the knee-joint capsule and become extravasated along the muscular plane above alluded to, is furnished by that class of cases in which the single application of a rubber bandage has resulted, in a few hours, in the complete disappearance of the effusion in the joint which has followed a severe injury to the knee-joint. The fluid has been heretofore claimed to have been reabsorbed, under these circumstances, in an incredibly short space of time, the joint resuming its normal appearance. In reality these are cases of rupture of the joint capsule occurring either from the injury itself directly or as a result of rapid effusion and hydrostatic pressure. This view is supported by the fact that this result cannot be produced in any other joint, nor yet in the knee-joint in cases in which the effusion is due to causes other than traumatism. There is no reason for believing, therefore, that, in this joint, pressure would hasten the resorption in this extraordinary manner, under conditions involving traumatic influences, and yet the same result not be at-

* Centralblatt f. Chirurgie, 1890, No. xii.

tainable in other joints or in this joint in effusions of a simple inflammatory character. The truth of the matter is that resorption does not occur at all; what really happens is that the fluid is forced through a rent at the point indicated and into the neighboring inter-muscular spaces. It may happen, however, that a distention of the upper recess may occur when a bandage is applied, no rupture having taken place, and while the pressure is kept up, the normal appearance of the joint is restored. It is not to be denied, likewise, that the application of an elastic or other bandage may be instrumental in producing reabsorption of the fluids both in the joint and along the plane of the vasti muscles; that it occurs, however, other than by the usual and slow process is open to doubt.

In addition to the occurrence of this accident there is another condition which furnishes a positive contra-indication to suturing the fragments, as an immediate operation in fracture of the patella. Allusion is here made to the occurrence of extensive and severe contusions in the neighborhood of the knee-joint itself. The lessened vitality of a part diminishes its resistance to infection even though the involved structures be highly organized. The occurrence of extensive contusions undoubtedly operates to lower the vitality of the tissues and hence invites the occurrence of septic infection. It is an open question whether such a thing as rigid and absolute asepsis in an open wound is ever obtained. It is more than probable that a typically aseptic wound is of rare occurrence. The question is simply one of dosage, as far as the entrance of infectious agents is concerned, and the conditions present in the tissues themselves and their power of resistance will decide the question for or against the patient, rather than the aseptic or antiseptic precautions taken or the activity of the germs which have run the gauntlet of the dressings applied. In spite of every effort an infinitesimal portion of the noxious agent may find its way into structures but little calculated, because of their damaged condition, to resist the inroads of infection. In addition to this the presence of a greater amount of fluid in the connective-tissue spaces, the opening up of these to a greater or less extent, and the increase of local heat undoubtedly favor not only the primary occurrence of infection, but the rapid spread thereof. In each individual case, therefore, it becomes a question of serious import, both to the surgeon and to the patient, whether or not a period of time should be chosen for the performance of the operation when the tissues have had opportunity to return, through the reabsorption of infiltrated materials, to their normal condition.

It certainly will not be claimed that the operation of suturing the patella is imperatively demanded in the very beginning of the treatment. Save in those rare cases in which the occurrence of a hæmarthrosis complicates the patellar injury, an immediate arthrotomy can but rarely be called for. Both the possibility of the occurrence of rupture of the joint capsule in the situation here described, indicating delay until this has been closed by nature's efforts, and the condition of the tissues in the neighborhood of the joint itself, should be taken into account in deciding the question of time of operating. If but slight contusion or other disturbance of the parts involved in the intended incision is present, the surgeon, before proceeding to operate, should turn his attention to the probable integrity of the joint capsule. The test of this is the behavior of the joint under a Martin's elastic bandage. If apparent rapid disappearance of the effusion follows the application of the bandage, this should be interpreted to mean that the joint capsule is ruptured beneath the muscular structures and that the effusion has been forced into the inter-muscular spaces. Under these circumstances, in the light of recent experience, the surgeon is not justified in proceeding with the proposed operation. In other words, the presence of devitalized tissues, or rupture of Riedel's space, or both, are positive indications for the postponement of the operation and the substitution thereof of ordinary routine measures of treatment for from ten to fourteen days. At the end of this time a secondary operation may be performed. *George Ryerson Fowler.*

PEDALIUM MUREX, L. ("Gokhru"). A shrub of the order Pedaliaceæ, indigenous to India and Ceylon. It is a tall, succulent annual, very common near the sea-coasts. The plant has long, stalked, opposite, ovate, toothed leaves and rather showy yellow flowers, produced singly in the axils of the leaves upon short stalks which are furnished with glands near the base. They have a small five-parted calyx with the upper lobe shorter than the others; a tubular corolla small at the bottom and wide at the mouth, expanding into five round lobes, the lowest of which is the largest; four stamens in pairs of different length, with the anthers forming a cross, and a thread-like style bearing a bifid stigma. Its fruits, which do not open when ripe, are four-sided and somewhat conical in shape, with four sharp prickles upon the corners near the base: they are divided into three cells, one of which is empty, while each of the others contains two seeds. All parts of the plant give off a musky odor when rubbed, and the plant when fresh contains an abundance of mucilaginous substance, upon which its medicinal properties depend. Simply drawing the branches through water is said to render it thick and mucilaginous. The seeds are used for making poultices. This plant has been proposed as a remedy well worthy of attention, as in the East it is highly prized. The infusion is employed extensively as a drink for the relief of dysuria, incontinence of urine, nocturnal emissions, and all painful and inflammatory affections of the urinary organs. The fruit or capsule is the part preferred. An infusion is made by adding one ounce of the bruised fruit to one pint of boiling water, allowing it to macerate for two hours, and then filtering. This quantity is sufficient for twenty-four hours, to be given in doses of two ounces. The infusion is to be freshly prepared each day. *Beaumont Small.*

PEGLI. This little place is a suburb of Genoa and is usually described as a Riviera resort. It is undeniably a more sheltered and equable place of residence than the windy city of Genoa. But it hardly belongs to the more typical Riviera resorts. For one thing, it is not yet the winter home of a large international colony of health-seekers, nor can it lay claim to being adequately supplied with all those comforts now demanded by exacting invalids. Nevertheless, the climate of Pegli has its advantages, and the luxuriant vegetation of the place clearly shows that it is much warmer than Genoa. It is also less dusty than some of the better known Mediterranean health-resorts, and the atmosphere holds more moisture.

It is claimed that sufferers from asthma do specially well at Pegli. Recurrent winter colds, neurasthenia, anæmia, and even phthisis are some of the principal diseases for which Pegli is said to offer favorable climatic conditions.

The Italians frequent Pegli in the summer on account of its fine sandy beach. An interesting feature of the place is found in the presence of many beautiful gardens belonging to wealthy Italians. The famous Villa Pallavicini has one of the most magnificent horticultural collections known. Dr. Sparks surmises that the asthmatics who do well at Pegli are sufferers from emphysema and bronchitis, but a number of other observers maintain that the purely spasmodic type is more apt to find relief there. The writer spent too little time at this resort to permit a personal judgment, but he believes that Pegli is a good enough intermediate station for travellers to or from the Riviera proper. It is not to be forgotten that Pegli is directly on the sea and that some invalids are unable to sleep on account of the noise made by the waves. The hotels are not of the best, but fairly satisfactory accommodations are provided. Prices are lower than on the French Riviera. *Edmund C. Wendt.*

PENTAL. This is the name applied to *Trimethylæthylen*, a product of amylenhydrate heated with acids. It (C_5H_{10}) occurs as a colorless liquid, of low specific

gravity ; its boiling point is 38° C. ; it burns with an illuminating flame and is readily inhaled without affecting the membranes of throat or passages. It is insoluble in water, but miscible in all proportions with alcohol, chloroform, or ether, and being inflammable like the latter, must be protected from possible ignition. It is exceedingly volatile, but does not decompose on exposure to air or light.

PEPSIN. The quality of this substance has improved more during the past few years than that of any other article of the Materia Medica. At the present date the tests and descriptions of existing pharmacopœias and dispensatories are wholly antiquated and inadequate. The United States Pharmacopœia of 1880 described as the best article at the date of its issue one that could only digest fifty parts of egg albumin in six hours. The new revision of 1890, when published, is expected to describe one capable of digesting three thousand parts in the same time, and another diluted one of three hundred times. There are pepsins upon the market that are fully equal to the task of digesting six thousand parts in six hours. The writer has tested a specially prepared sample that succeeded in converting twenty-five thousand times its own weight of albumin into peptone in standard time. The production of so high a grade as the last mentioned is at present too costly to enable any manufacturer to put it upon the market at a reasonable price. It shows, however, how far we yet are from an absolute pepsin.

Notwithstanding the very great proteolytic power of such an article, there are reasons for believing that it is still one-half foreign admixture. What, then, must have been the quantity of impurity present in the supplies of a decade ago which had only one five-hundredth part of this strength ? Until a perfectly pure article has been isolated nothing can be done toward determining the chemical composition of this ferment.

It has recently been ascertained that pepsin, like albumin, is coagulated by heat. Slightly acid solutions of it containing a small amount throw down a light, flocculent precipitate on boiling, if mucus, sugar, or other substance capable of holding it in suspension are absent. Where these are present the solution merely acquires a milky appearance as a result of the application of heat. Using this as a test the eye can readily learn how to distinguish the relative proteolytic value of most brands, and the time consumed, instead of extending into hours, need occupy but a few minutes. The old plan of ascertaining the value of a pepsin by giving it an excess of albumin to act upon and then drying and weighing the residue so as to find how much was converted into peptone during six hours is now abandoned. The results were always untrustworthy. Now, after several trials with varying proportions, the exact amount capable of completing digestion within the time named is what is sought for.

Since the best pepsins of a decade ago now rank as very inferior, the description of a good article now must differ from that given then. A first-class article to-day should be totally free from any offensive odor ; easily soluble in one hundred parts or less of water acidulated with 0.2 per cent. of hydrochloric acid ; should not become wet or sticky in damp weather, and should have a mildly acid, agreeable taste, usually followed by slight bitterness. If in scales they should be nearly or quite transparent and of a pale, straw color. If in powder it should be fine and white. The reaction should never be alkaline, but always slightly acid or rarely neutral. When a small amount is burnt on platinum foil, only a trace of residue should be left. Any pepsin that fails to answer to these requirements cannot be expected to give the best results. Offensive smelling, insoluble, and easily putrescent pepsins may be positively injurious instead of beneficial to patients. Highly hygroscopic ones contain an excess of peptone and give unsatisfactory results unless very large amounts are used.

Pepsin is incompatible in some degree with nearly every remedy. Some substances completely destroy it. Such alkaline remedies as bicarbonate of soda, carbonate and bicarbonate of potash, solution of potash, Fowler's solution, carbonate of ammonia, aromatic spirits of ammonia, lime water, and chalk mixture should never, on any consideration, be prescribed with it. The slightest alkalinity renders a pepsin solution totally inert. An actual examination of the prescription files of several pharmacies shows that to a large proportion of reputable physicians this fact is not known. Bicarbonate of soda and pepsin constitute a favorite combination of theirs. Probably the excess of soda benefits the patient, and they give the credit to the combination. Iron reduced by hydrogen and all substances that combine directly with acids check the action of pepsin by rendering the solutions neutral. They do not, like alkalis, destroy the ferment. The following inorganic substances in a solution of pepsin and albumin inhibited digestion the number of minutes given when only fifteen centigrammes were added to fifty grammes. When no drug was present the digestion was complete in two hours. When the drug named was present digestion was delayed beyond the two hours the number of minutes given :

	Minutes.		Minutes.
1. Chloride of ammonium	320	26. Benzoate of potassium	110
2. Chloride of calcium	250	27. Sulphide of potassium	650
3. Chloride of sodium	200	28. Sulphate of ammon. and alumin	750
4. Chloride of antimony	160	29. Sulphate of copper	720
5. Chloride of potassium	90	30. Sulphate of magnesium	690
6. Chloride of lithium	60	31. Hypophosphite of manganese	80
7. Bromide of iron	360	32. Hypophosphite of sodium.	60
8. Bromide of ammonium	200	33. Hypophosphite of potassium	40
9. Bromide of lithium	120	34. Chlorate of sodium	280
10. Bromide of sodium	100	35. Chlorate of potassium	200
11. Bromide of cerium	90	36. Acetate of sodium	30
12. Bromide of potassium	60	37. Acetate of ammonium	30
13. Iodide of potassium	200	38. Sulphocarbolate of zinc	140
14. Iodide of arsenic	190	39. Sulphocarbolate of sodium.	80
15. Iodide of sodium	180	40. Phosphate of iron	60
16. Iodide of ammonium	170	41. Phosphate of sodium	30
17. Iodide of lead	60	42. Salicylate of sodium	690
18. Iodide of calcium	5	43. Salicylate of potassium	560
19. Nitrate of sodium	450	44. Valerianate of ammonium.	60
20. Nitrate of potassium	390	45. Valerianate of zinc	30
21. Nitrate of strontium	380	46. Ammon. citr. of iron	410
22. Nitrate of uranium	310	47. Ammon. citr. of bismuth	90
23. Benzoate of sodium	160		
24. Benzoate of ammonium	160		
25. Benzoate of lithium	140		

Tinctures and fluid extracts have a decided retarding effect beyond that of their contained alcohol. Essential oils from the same botanic orders retard in very nearly the same degree, while those from unlike orders are broadly contrasted. It is evident from this that pepsin is best administered alone.

The habit of giving pepsin in every form of deranged digestion merits only condemnation. Its long-continued use in chronic cases is also generally reprehensible. When more proteids have been swallowed than the stomach can unaided dispose of, then it is beneficial, but the dose must be commensurate with the work required of it. A few grains of weak, saccharated pepsin are useless. As it is in no sense poisonous, there is no danger of an overdose. All the danger lies the other way. Give plenty in a single dose after the meal and then stop. As a means of dissolving diphtheritic membranes and allowing thereby antiseptic sprays or gargles to reach the imbedded germs, it has been highly lauded. For this purpose the most powerful brands should be used, so as to gain prompt results. In surgical practice it has proven an efficient agent in removing gangrenous tissues. The various elixirs and wines of pepsin are of questionable value in any case unless the alcohol itself is reckoned upon for its utility. The quantity in any of these is too small to give calculable results. The average saccharated pepsins, containing, as many of them do, scarcely enough of the ferment to digest little more than an equal weight with themselves of albumin, can only answer in a prescription as a placebo. With the advance in the quality of pure pepsins these have deteriorated. It is time they should be dropped entirely. In no other medicine do physicians voluntarily order adulterated goods, and what is the large bulk of sugar of milk but an adulterant ?

Robert G. Eccles.

PERITONITIS, SEPTIC. The terms "septic peritonitis" and "suppurative peritonitis" are apt to be confused. Indeed, it is difficult to make a clear distinction between these two forms of disease. With our present knowledge we must grant that the cause is the same in each form, viz., the entrance into the peritoneal cavity of the pyogenic bacteria in sufficient number to cause an attack of peritonitis which differs in all its features from the plastic or adhesive form. The streptococcus pyogenes is the variety most frequently and most abundantly found; less often and less abundantly the staphylococcus pyogenes aureus; and the bacillus coli commune, and occasionally other varieties, are present. Our knowledge is as yet imperfect, and it is to be hoped that we shall soon be in a position where we can judge in at least an approximate manner of the gravity of the attack from the presence of certain varieties of bacilli. Attacks of these forms of peritonitis differ so much in duration and in severity that it would be of the greatest service for our prognosis and treatment of such cases if we could estimate the character of the attack from the existence of certain bacteria in the exudate. Such information would also be of great diagnostic aid in telling us which of the abdominal organs had been the etiological factor in the case. The manner in which these organisms gain entrance into the peritoneal cavity has been fully described in the original article on peritonitis. Neither there nor elsewhere, as far as I know, is there any definite description of how we may reach conclusions as to the cause of the disease in any specific case. I do not now refer to cases which may have been watched for weeks or months and suddenly develop peritonitis, but to those patients which every surgeon connected with hospitals with a large ambulance service must frequently encounter, where cases are first seen after septic peritonitis has been fully established, and where no previous history of value can be obtained. Such cases are met with in private practice also, and anyone who has encountered them must know how difficult they are of diagnosis.

The development of the disease is very much favored by lesions or diseased conditions of the peritoneum. The presence of fluid, especially blood, also favors the development of the pyogenic bacteria. On this account, after abdominal operations great care is taken to render the cavity as clean and dry as possible. Loose shreds of tissue with low vitality, and also tissue which will become necrotic, afford conditions which favor the attack of peritonitis.

The tendency of suppurative peritonitis is to become localized, septic peritonitis is always general. If we acknowledge that the cause is the same in both cases, we should on theoretical grounds arrive at certain conclusions to explain why in certain cases suppurative and in other cases septic peritonitis results. The two forms of disease, however, are so closely allied that in certain cases it is difficult to say which is the proper term. It seems reasonable to conclude that when the disease assumes a suppurative form the poison, consisting of the pus microbes, is either less in amount or less virulent in quality, or else that the local conditions are less favorable for the spread of the poison and its absorption into the circulation. In the septic form the development of the bacteria is so rapid and extensive that a general peritonitis is immediately established, and the absorption into the blood is so rapid that the system is at once overwhelmed by the poison.

(*a*) *The Septic Form.*—This is always diffuse or general. In many cases the disease is so rapidly fatal (12 to 24 hours) from acute sepsis, that but little evidence can be obtained at the post-mortem examination. The intestines are deeply congested, somewhat distended, and the exudate is but scanty—a cloudy, sometimes bloody serum with particles of lymph, which on microscopical examination is found to be rich in pus-cells. While many of such cases die at an early stage, yet it seems certain that the disease may begin in this form though with less virulence, and progress to the putrid purulent peritonitis, with abundant foul-smelling, purulent exudation, and with the intestines covered by thick layers of lymph (coagulated fibrin), which also floats in large flakes throughout the fluid.

The first symptom of the disease varies according to the cause. If from some perforation, it may be ushered in by signs of collapse, with severe localized pain, subnormal temperature, and rapid feeble pulse (150). In other cases if the perforation be a minute one, or after surgical operations, the onset is less sudden and often painless. The temperature may vary but little, and the only indication at first may be the rapid small pulse and the look of extreme anxiety which is expressed in the face of the patient. In either case vomiting, hiccough, or "gulping up" of fluid, is one of the first and most important and most distressing symptoms. At the same time the abdomen becomes rapidly tympanitic, and considerable discomfort is produced from this cause. The temperature is a very unreliable symptom. Occasionally it remains subnormal during the entire course of the disease in the rapidly fatal cases. More generally there is a slight elevation, but it seldom rises above 101°, unless perhaps, ante mortem. In my experience I have met with many cases where for days the temperature ranges between 98½° and 100°F, and never has risen above this latter point, even when the patient has lived for six or seven days. A chill is not common, cyanosis is a common symptom in the very severe cases, and is a sign of a fatal termination not far off. The most diagnostic symptoms are the gulping up of greenish material into the pharynx, the vomiting, and generally the obstinate constipation and the peculiar anxious look of the patient. As a rule, the mind remains clear, the senses acute, and the voice strong. In many patients, especially where the disease occurs after abdominal operations, their appearance to one unaccustomed to such cases is very deceptive. The face, beyond a pinched, eager look, does not show evidence of severe disease; questions will be asked and answered intelligently and clearly; and it may not be recognized until the hand is placed upon the pulse that such patients have but an hour or two to live. In other cases the restlessness is extreme, the countenance expresses the greatest distress, and the extremities are cold and cyanosed. This latter symptom is sometimes very marked, and may appear twelve or twenty-four hours before death results. It is as marked in some patients as is the algid stage of cholera, and when it appears, perhaps early in the attack, is a symptom of the gravest significance.

(*b*) *The Suppurative Form.*—In many cases this is probably a later stage of what has been termed the septic form. For certain reasons the disease has not assumed such a virulent form as to end fatally before free suppuration has been established. What these reasons are we do not know. Whether it is a peculiarity in the general condition of the patient, an environment unfavorable to the development of the germs, the introduction of a smaller quantity or of less poisonous forms of germs, we do not know. In other cases some of the causes unfavorable to the propagation of the germs are still more predominant, and instead of a general suppurative peritonitis, the serous membrane tries to localize the poisonous collections by casting out a fibrinous exudation, and adhesions are thus formed which surround the collections of pus and prevent general infection. These may be small and numerous in different parts of the peritoneal cavity, or one large collection may occupy nearly all the cavity, the intestinal coils being crowded aside and, united by adhesions, form the walls of this intra-peritoneal abscess. Such cases cannot be called examples of general suppurative peritonitis. The prognosis, if proper treatment be used, is vastly more favorable than in the diffuse form, and the symptoms less severe. A case may progress for some days in this manner as a localized suppurative peritonitis, and suddenly the diffuse form develop from rupture of the abscess into the general peritoneal cavity. An abscess, which at first was extra-peritoneal, may also rupture and discharge a large quantity of pus into the peritoneal cavity and excite at once general suppurative inflammation, varying in severity with the virulence of the pus which has excited the attack.

The symptoms are more pronounced than in the form

described as septic. Occasionally the disease begins with a chill. Pain is common, indeed nearly always present at some stage of the disease. At first it may be localized: later it becomes general. The temperature generally rises, and may reach 103° or 104°. Other cases, however, have comparatively little fever (100° to 100½° F.). Vomiting, tympanitic distention, and constipation soon follow. Should the disease be localized the symptoms become less severe. The temperature may remain as high, but is intermittent, and often accompanied by chills and sweating. The vomiting, however, subsides to a certain extent, and constipation may give place to diarrhœa. The tympanites also diminishes. Should the disease begin and continue as a general or diffuse peritonitis, the symptoms continue without much change, and the patient gradually succumbs to exhaustion and toxæmia. Death may result in three or four days, or may be delayed for from six to eight days.

Prognosis.—In both forms of general peritonitis the prognosis is absolutely bad. Without surgical interference a fatal termination is certain. Even with early and skilful surgical interference the prognosis still remains very unfavorable. The great majority of such cases die. If the suppurative form remains localized the prognosis is changed, and then, if appropriate surgical treatment be adopted, is favorable.

Treatment.—Medical treatment is of no avail in the treatment of *general* peritonitis, whether called septic or suppurative. Before the peritonitis is fully established drugs are of some avail. In the form which threatens the patient after laparotomy an early dose of some cathartic will often ward off the attack, and where tympanitic distention, and perhaps vomiting, show themselves after such operations, a cathartic should be at once administered. If we can ascertain that a perforation or rupture of some abdominal organ has taken place, opium should be administered for the purpose of localizing the infectious process, and, if the perforation is a small one, the peritonitis may, by this means, be circumscribed. In all other cases opium is injurious. By it the symptoms are masked, diagnosis made more difficult, and paralysis of the intestines favored by the narcotic influence of this drug. If the perforation has been sudden and extensive, stimulants may be needed to revive the patient from a condition of collapse. If the disease is clearly a general peritonitis, laparotomy (cœliotomy) is the only treatment which will give any hope of cure. The earlier in the course of the disease that the abdomen is opened the better the chances are for recovery. If left to itself, or to treatment by drugs, the disease is certainly fatal, and therefore laparotomy should be resorted to in cases where otherwise operation would be an unjustifiable procedure. The abdomen should be opened at as early a date as possible in all cases, unless the patient is so weak that death on the operating-table is inevitable. In every case the desperate nature of the disease, and the possibility of cure by laparotomy, should be explained to the patient's friends. The surgeon may be apt to shrink from operation in such cases where a fatal termination is most probable, and death during or immediately after the operation possible. It is his duty, however, to give such patients their only chance of relief, even if it be a very slight one, and the conscientious man will so regard it. Successful cases have been rare, and the majority of them have been operated upon within the first forty-eight hours, but a few cases operated upon as late as the fourth and fifth day have recovered.

Successful results have been reported where the patients seemed to be almost beyond hope, with the pulse at 140 and the temperature subnormal. In one of my own successful cases, operated upon on the second day of the attack, the temperature was 96¼°, pulse 140, and extremities cold and cyanotic. It is only within recent years that the utter hopelessness of medical treatment and the possibility of cure by operation have been fully recognized. For this reason the cases have been generally handed over to the surgeon after many precious hours have been wasted in trying to control the peritonitis. If cases could be operated on at an earlier stage the results would be more favorable. Even if there be some doubt as to the correct diagnosis, an exploratory laparotomy should be performed, for almost surely some condition will reveal itself which can only be relieved by operation. The differential diagnosis between intestinal obstruction and peritonitis is very difficult to determine. The same symptoms accompany each disease, and at an early stage it is often impossible to distinguish between these two conditions. In doubtful cases the question will nearly always be between obstruction and peritonitis, and operation is as much demanded in one case as in the other. It is impossible to state what proportion of cases recover. Probably all the successful results are reported, and not nearly all the fatal ones. A score or more of recoveries from general septic peritonitis have been reported out of several hundred operations. In my own experience I have done laparotomy on fourteen patients for diffuse septic peritonitis, and eleven have died and three recovered. This may represent perhaps a fair average of the result of other operators.

Operation.—An anæsthetic should be administered, at least until the abdominal wall has been cut through. The incision should be made in the median line, three or four inches in length. If no indication as to the cause exists, the incision should be made between the umbilicus and symphysis pubis. If symptoms point to a perforation in the stomach, it should be made over this organ: if to disease of the appendix vermiformis, then it should be made external to the right rectus muscle. When the peritoneum has been opened the purulent fluid will escape, and perhaps gas, if the intestine or stomach has been perforated. The fluid should be allowed to escape, and a rapid search made for the cause. If the patient's condition is good this search may be carefully carried out, and the cause removed if possible. Generally, however, the patient's condition is such that prolonged search is unjustifiable, and the operation must be completed as rapidly as possible. The remainder of the operation consists in freely irrigating, with hot sterilized water, the entire abdominal cavity. In certain cases the intestines will have been removed in the search for the original lesion, and in patients whose strength will admit of it, it is often advisable to do this in order to cleanse more thoroughly the abdominal cavity. Often, however, this is unjustifiable, and the irrigation must be made without removing any of the intestinal coils. A forcible stream from the irrigator is carried to different points of the cavity, and an attempt made to wash out by the hand as much of the secretion as possible. The water runs out either through the open abdominal wound or through other tubes inserted for this purpose. The water is allowed to run until it emerges comparatively clear. Two full-sized drainage-tubes should then be left projecting out of the abdomen, one in the upper and the other in the lower angle of the wound. In addition to these, counter-openings may be made in each loin, and drainage-tubes inserted in these regions to effect more perfect drainage. The abdominal wound is then closed and the patient freely stimulated per rectum. The after-treatment consists in free and full stimulation by hypodermatic injections, by rectum, and later by the mouth. This must generally be continued vigorously for days. As soon as the stomach can retain cathartic medicine the bowels should be freely moved. Such is the general plan of procedure. Many modifications have been tried, but without important results. Antiseptic solutions alone have been used for irrigation, or have been followed by hot water. Irrigations repeated every hour or so have been employed for one or two days after the operation. If the intestines have been removed from the abdomen it may be found necessary to open the gut by small incisions to give vent to the gas before they can be returned. Puncture by perforated needles is comparatively useless for this purpose. Drainage may be accomplished by iodoform gauze, but as a rule tubes are preferable. They drain for twenty-four, perhaps thirty-six or forty-eight hours, and are then shut off from the general cavity by intestinal adhesions, and may be removed.

What is accomplished by this treatment? The secre-

tion is in part, at least, removed, and though the poisonous microbes can never be completly exterminated, yet their number is much diminished and their culture fluid very much diluted. By after-drainage the secretions, and with them a certain number of bacteria, escape from the abdomen instead of remaining shut up to add to the toxæmia which already exists.

By removal of pressure the sufferings of the patient are lessened, and the action of the heart and lungs improved. An opportunity is also given to remedy the original lesion, and this may be easy to accomplish, and often is of vital importance. In most of the cases, unfortunately, a sufficient dose of the poison has been absorbed previous to operation to overwhelm the patient, but in a small proportion the vital force is sufficiently strong to conquer the toxæmia, and the result is recovery. It is true that this proportion of successful results is small; perhaps ten per cent. of recoveries would be a fair estimate. It is certain, however, that could patients be operated on at an earlier period the result would be more favorable. It is especially upon physicians that this fact should be impressed, for as a rule it is the family physician who first sees these patients, and it is his duty to be alive to the urgency of the case and the necessity for immediate laparotomy.

Andrew J. McCosh.

PERITONITIS, TUBERCULAR. The peritoneum is very susceptible to tubercular infection. This membrane is more easily infected by the tubercular bacillus than it is by the pyogenic bacteria. It can safely dispose of a considerable number of the latter bacilli, but a very small inoculation with the former is enough to excite a tubercular process.

Etiology.—The direct cause is the bacillus tuberculosis. Tuberculosis of the peritoneum is rarely primary. As a rule the process has extended from some other organ; in some cases by direct contact, in others by metastasis. The primary disease may be situated in the intestinal tract, in the lungs, in the joints, in the bones, in the sexual organs, both male and female, or, indeed, from any tubercular process in the body the peritoneum may become secondarily infected. In young children the original focus is apt to be situated in the intestines. In adult females the process most often extends from the Fallopian tubes; in adult males from the lungs. On theoretical grounds it would seem probable that tuberculosis of the peritoneum would rapidly disseminate itself through the system. This, however, is not the case. There is a distinct tendency to limitation.

Age.—No period of life is exempt. It may occur in very young children and in old age. The most common period for its development is between the ages of eighteen and forty-five.

Sex.—Statistics differ as to the relative liability of the two sexes to the disease. Of patients operated on, the great majority have been females, only about twelve per cent. males. Before the twelfth year, or before the genital organs have become developed, about an equal number of males and females have been subjected to operation. In the autopsy-room, however, the proportion is reversed. The number of cases among males is largely in excess of that among females, in the proportion of about three to one, according to most observers. The reasons given for this discrepancy are that the abdomen of females is more easily, and generally more carefully, examined; that the diagnosis in a certain proportion of cases among females has been accidentally made when the abdomen has been opened on the supposition that a tumor existed; that in males the peritoneum is apt to be infected from the lungs or intestines at a later period of the disease, when the secondary involvement is completely overshadowed by the original disease. From observations, however, by clinicians and surgeons, the disease seems to be more common among females, and careful investigation on the part of the pathologists will probably prove that this view is correct.

Pathology.—Various anatomical classifications have been made. Osler divides the disease into the following categories:

1. Acute miliary tuberculosis, characterized by a sudden onset, a rapid development, and a serous or sero-sanguineous exudation.

2. Chronic caseous or ulcerating tuberculosis, characterized by larger tubercular growths, which tend to caseate and ulcerate, leading often to perforations between the intestinal coils and a purulent or sero-purulent exudation, often sacculated.

3. Chronic fibroid tuberculosis, in which the process may from the outset be subacute, or may represent the final result of the miliary form. There is little or no exudation.

In the first form the peritoneum is thickened and everywhere studded with miliary tubercles, there is present a considerable amount of ascitic fluid, and the coils of intestine may become agglutinated. In the second form the intestines are apt to be matted together, their walls thickened, œdematous, and often covered by a thick, grayish membrane. There are apt to be local accumulations of fluid, generally purulent, shut off by adherent coils of intestine. This process may be limited, or all the intestines may be so matted together and covered by thick membrane and caseous masses that it is difficult to distinguish their coils, and the impression may be given in such cases, before the abdomen is opened, that a solid abdominal tumor is present. In such cases the abdominal wall is apt to be œdematous, and is boggy to the touch. In all forms the mesenteric glands may be enlarged, and often to such a size that they can be distinctly felt by abdominal palpation.

Osler calls attention to "omental tumors," which result from a puckering up of the omentum till it forms a roll below the transverse colon. Such cases are seldom accompanied by much exudation, and are apt to be mistaken for malignant growths. It is important to decide in what cases the disease is confined to intra-peritoneal tissues. It is more apt to be local in females than in males, on account of the greater liability of extension from a Fallopian tube. Probably in twenty-five to thirty per cent. of all cases in women the disease is confined to the peritoneal cavity. In males the proportion of cases with such limitation is very small.

Symptoms.—The mode of onset of the disease is very variable. It may be acute and sudden, or it may be so uneventful and its course so insidious that its nature is not suspected until revealed by autopsy or operation. Between these two extremes the disease may be ushered in by symptoms which are very variable both in their character and severity. In the acute form the symptoms from the first are severe. There may be a chill, though as a rule this is absent, and elevation of temperature is the first sign of importance. This may reach from 103° to 104.5° F., and gives rise to the subjective symptoms which accompany fever. At the same time the signs of an ordinary attack of acute peritonitis show themselves: abdominal pain and tenderness, tympanitic distention of the intestines, rapid, small pulse, and occasionally vomiting. Cases with such a severe onset are not common, and generally occur in the course of an acute miliary tuberculosis. The disease is more apt to assume a semi-acute form. In such patients a general malaise with slight elevation of the evening temperature is first noticed. The fever gradually and steadily increases, and for two weeks or more may be the only prominent symptom. The tongue is coated and the prostration considerable. By the third week the evening temperature is apt to be about 102.5° or 103° F., and the morning temperature a degree or two lower. In such cases the symptoms are almost identical with those of typhoid fever, and for several weeks it may be impossible to make a correct diagnosis, especially when diarrhœa is present, as is sometimes the case. Generally about the third week attention is attracted to the abdominal distention, which is partly due to exudation and partly to tympanitic distention. This symptom increases, and soon a peculiar boggy feel is derived on abdominal palpation, or perhaps a distinct sense of fluctuation. In the latent form,

with the exception of slight malaise there are no symptoms of importance until it is noticed that the abdomen begins to enlarge. This distention increases slowly, but is accompanied by so little discomfort and so little fever that a diagnosis of cyst, probably ovarian, is apt to be made, or perhaps of ascites due to some other cause. In such cases, however, there is generally a slight elevation of the evening temperature, perhaps of one or two degrees (F.). It is very apt to be overlooked. In a few cases, on the contrary, a subnormal temperature may be present and may continue for several weeks. Of the special symptoms ascites is the most common. In nearly every case there is a certain amount of fluid in the peritoneal cavity. It is generally light straw-colored, occasionally bloody, and usually is free in the general cavity. In cases where caseous and ulcerative processes are present there is very little fluid exudation, and what there is is generally purulent. The temperature is a very variable symptom. In most cases there is a slight elevation, in a few, marked febrile reaction, and yet in others, subnormal temperature. Abdominal pain and tenderness are not common. Except in the very acute cases, which are rare, no severe pain is experienced. In many patients a feeling of discomfort exists from the commencement, and will generally increase in proportion to the amount of exudation. Tympanites is a rare symptom. Pigmentation of the skin, especially of the face, has been noticed in a few cases (Osler). Attention is called by Edebohls to plaque-like thickenings of the subperitoneal tissues.

Diagnosis.—The history of the patient and the presence of tuberculosis in other organs are the most important points in arriving at a correct diagnosis. The acute form must be distinguished from idiopathic peritonitis. The latter disease progresses in a more violent and rapid manner, and is accompanied by more tympanites and by persistent vomiting. The subacute form must be distinguished from typhoid fever; inoculation may be of aid. The latent form must be distinguished from abdominal cyst. In certain cases this is impossible except by exploratory laparotomy. The fluid may be more or less encysted. Reliance must be placed on palpation by an experienced hand; percussion in abdominal tumors is but of little value. Mistakes between these two conditions are constantly made by the most experienced observers, and much of our knowledge of the disease has been derived from such mistakes.

Prognosis.—Without surgical interference the prognosis is bad. Spontaneous healing is not uncommon in children, but in adults it is very rare. If laparotomy be resorted to as a curative measure, the prognosis is very much improved and may be said to be favorable. The majority of patients operated on are permanently cured of the peritoneal tuberculosis. In my own experience I have had two patients who at the end of three and five years respectively after operation were in perfect health. In another case, at whose operation I acted as assistant to Dr. T. G. Thomas, eleven years have elapsed since the laparotomy, and there is no sign of return of the disease. Cases have been reported in perfect health at the expiration of more than twenty years after operation.

Treatment.—In children who have been living in an unfavorable environment dietetic and hygienic treatment may be tried for a time, and will occasionally result in a cure. In all other cases, where the other organs are free from tubercular deposits, abdominal section (cœliotomy) is the only appropriate treatment. It should be resorted to as soon as the diagnosis has been made. In cases where other organs are diseased each case must be decided on its own merits. If the disease is such as to allow the patient but a short lease of life the peritonitis had better be disregarded. If the disease, however, is in its earlier stages, and is not such as will lead to a speedily fatal termination, an attempt should be made to cure the peritonitis by means of laparotomy. I have under observation one woman on whom I operated two and a half years ago. She had then, and still has, a consolidation of the apex of one lung. The process, however, is but slowly progressive, and she has not had a sign of return of the peritoneal tuberculosis which at the time of the laparotomy was pronounced.

The method of operation is as follows: An incision should be made in the median line, between the symphysis pubis and the umbilicus, large enough to admit the hand, or at any rate two fingers. The ascitic fluid should be allowed to escape by turning the patient on the side. A complete diagnosis should now be made by the hand thrust inside the peritoneal cavity. If the original focus can be ascertained and removed, this should be done. If it be a Fallopian tube, this can usually be done with comparative ease. If it be an intestinal ulcer or caseous lymphatic glands, the operation may be attended with great difficulties. No rules can be laid down for such cases. The cause should be removed if possible; but this must be decided by the surgeon at the moment of operation. The entire peritoneal cavity should now be irrigated with hot sterilized water. This should be thoroughly carried out, and continued until the water comes out perfectly clear. A glass drainage-tube should be inserted in the lower angle of the wound and the abdominal incision closed by suture. It is well before closure of the abdomen to remove a portion of membrane for future microscopical examination. The drainage-tube should be left in as long as it drains the peritoneal cavity. Its action in this capacity will probably cease in from two to five days, and it should then be removed. Occasionally, however, drainage will continue for many weeks. This on the whole is the most reasonable method, but many modifications have been practised. The results, however, are not more favorable. Instead of plain water different chemical solutions are used, most often Thiersch's solution (boro-salicylic acid solution). The peritoneal surface may be carefully sponged or wiped with gauze. Iodoform pencils may be left in the abdomen. Drainage may be made by iodoform gauze. An emulsion of iodoform in glycerine may be injected, and the good results which are now obtained from the use of this drug in tuberculosis in other parts, especially in joints, would be a strong argument in favor of its use in the peritoneal cavity.

While it is certain that laparotomy effects a cure in many cases, it is uncertain how this cure is brought about. Several theories have been offered in explanation, but none are thoroughly satisfactory. The behavior of the tubercular process in the peritoneum is so unlike that in other organs that some doubt has been cast upon the diagnosis of such cases. In so many of them, however, has microscopical and bacteriological examination proved the existence of the bacillus, that we must believe that the diagnosis in the great majority of cases has been correct. Many tumors of the abdomen, especially of the female genital organs, behave in a somewhat similar manner, for it is certain that simple abdominal section will result in marked improvement and in occasional cure of solid growths of the uterus and ovaries, and in malignant disease a decided amelioration of the symptoms often follows and continues for months. The growth of the tubercle bacillus is undoubtedly stopped, and retrograde curative changes induced by the laparotomy. Osler says: "In some way the operation renders the condition of the peritoneum more favorable to the fibroid changes by which alone healing is induced." Phillips claims that it results from encapsulation of the tubercular tissue by means of connective tissue, as occurs in tubercular joints. Such, however, is not always the process, for cases have been reported where masses of considerable size have entirely disappeared and no trace of tumors or irregularities remained, such as would have been found had the tubercular material been surrounded or replaced by connective tissue. In a case of my own, at the time of operation, in addition to several quarts of ascitic fluid, there existed many nodules in the abdominal cavity, varying in size from a pea to a hen's egg. Two years later I did a laparotomy in this patient for strangulated hernia, and took advantage of the opportunity to make a thorough examination of the peritoneum, which was found everywhere smooth, and not a nodule or irregularity to be felt. A similar case

has been reported by Schede. We know that the peritoneum has a great capacity for the absorption of poisonous substances. The operation removes pressure by the escape of the ascitic fluid, and in this way a certain stagnation in the blood-vessels may be removed. Sponging and irrigation, and perhaps the entrance of air, causes a certain irritation of the vessels and nerves of the peritoneum, and an increased capacity for absorption may be thus imparted to the lymphatics and blood-vessels. This reasoning, however, is purely theoretical, and some better explanation is needed of the processes by which a cure is effected. *Andrew J. McCosh.*

PERSONAL IDENTITY OF THE SOLDIER. This subject, with the methods that may be used in establishing identity, has an ever-present interest, not only to the medical, but to every other officer of the army: to the medical officer in drawing his attention to the physical peculiarities that the necessarily painstaking examination may develop, and in fixing the habit of minute search for surface indications of diseased action or of defects in person that might otherwise readily escape notice in an ordinary inspection; to other officers in the facility afforded for recognizing men who, having previously served in the army through partial or full terms of duty, seek readmission, but for reasons of their own conceal the fact of a previous service; in other words, who attempt a fraudulent enlistment. This class is made up of deserters, of men who have been discharged by sentence of military courts or by order of the Department "for cause" or for disability, or those who have served a term of imprisonment as military convicts, an undesirable class whose members are to be kept out of the army by any means that can be devised for the purpose.

Except for the identification of deserters, who when convicted could be legally punished for their crime, there seemed but little profit in applying any test to the remainder of this class of delinquents, because the imperfection of the law was such that if discovered there could be no punishment for them other than by dishonorable discharge, which really gave an offender the opportunity to repeat his infamous practice; a sufficient number, however, remained undiscovered until their desire to repeat their fraud led them to desert, and the increase thus made in the percentage of this crime, together with its demoralizing effect upon the army, led the authorities to seek a reliable system by which this portion of the class at least might be eliminated from the service. After careful observation and a discussion of the many methods presented, the system devised by the writer was finally adopted and has been attended with a success in its application that has given universal satisfaction. The passage by Congress of an Act making fraudulent enlistment a military offence and punishable by court-martial under the 62d Article of War, now extends the usefulness of the system and enables it to be of practical effect in dealing with the entire class.

In the discussion of the subject four methods were proposed, viz.:

1st. By tattooing at a designated spot the person of every recruit.

2d. By photographing each recruit.

3d. By the application of M. Bertillon's system of bodily measurements.

4th. By a systematic record of bodily markings and peculiarities.

The first method, which was suggested and urged by many, among whom were officers of rank and influence, was met by legal objections and by the probable danger of specific or septic infection of the recruit in the operation; it was accordingly promptly laid aside.

To the second, objection was made that the presence or absence of the hair and beard, the facial expression, the physical condition of the individual, the dress, the pose, the light in which the pictures might be taken, would present such differences between the present and the past photographs that recognition would be very difficult, if not almost impossible, and this, added to the other difficulty in systematizing or arranging the pictures for easy and rapid comparison, demonstrated its impracticability.

To the third, or so-called "Bertillon method" of bodily measurements, there was the ethical objection that it was devised and used solely for the identification of criminals. "The citizen who desires to enter the army of the United States does so under the belief that he is engaging in an honorable profession, and the code which is presented to him, both in the language of his enlistment contract, in the Articles of War, and in the Regulations of the Army, is drawn with a view to sustain and strengthen this belief. The effect of meeting him at the threshold of his enlistment with a system of identification which is stamped with criminal associations, and presupposes an intent on his part to violate his contract, cannot but be fatal to his honorable purpose, and result either in driving him in disgust from the recruiting rendezvous, or in suggesting a future escape from a service into which present necessity has forced him." While excellent results are said to have been obtained by this method, there was further objection to it because of the impracticability of securing properly instructed men to use the required instruments of precision, and because of the expense in procuring these instruments.

Recruiting in this country is carried on not alone at fixed stations in cities, but by peripatetic parties in the rural districts as well as at all military posts. The *personnel* of the recruiting service is constantly changing with ever-shifting military exigencies, and neither the opportunities to instruct nor the men to be instructed in anthropometry are obtainable. All recruits are promptly assigned after enlistment to military stations, where their thorough physical examination is made by the officers of the Medical Department on duty thereat, and the opportunity is thus presented of securing, through responsible and reliable officers, professional accuracy in determining the existence of bodily markings; this being done, moreover, with the least offence to the sensibility of the recruit, who naturally and willingly submits to complete exposure of his person in the anticipated examination of his physical fitness for military duty.

To the fourth method there was no apparent objection, and its basis had the favorable opinion of M. Bertillon, who says that "they (permanent bodily marks) offer a greater guarantee for identification than measurements, and that they would take their place altogether if it were possible to use them as a basis for classification." Upon its adoption the following order was issued by the War Department placing it in operation:

"Hereafter, a record of such indelible or personal marks as may be found upon the person of an accepted recruit will be made upon an outline figure-card, as illustrated upon accompanying pages of this order, and forwarded promptly on completion to the Surgeon-General of the Army. No letter of transmittal is required. The outline cards will be furnished by the Adjutant-General.

"The examination and record of marks of recruits belonging to the General Service will be made by the medical officer at a depot; of recruits enlisted at military posts, by the post or attending surgeon; and of recruits enlisted at other places where the services of a post or attending surgeon cannot be obtained, by the enlisting officer. In the cases referred to in section one, the record of marks will be made at the second examination.

"The object of this record is to obtain evidence for the identification of men who have had previous service in the army, and its successful accomplishment depends upon a rigorous precision in noting on the card all personal markings or peculiarities. The following directions should therefore be strictly observed:

"Directions for Recording the Personal Markings on Accepted Recruits.—Make a careful search of the body, front and rear, on each side of the median line, separately, commencing at the scalp and ending at the foot, for any scars, moles, tattoo marks, etc., that may exist, indicating their position on the body by a dot made with pen and ink at a corresponding point on the figure-card; on its blank fly-leaf note the *general inclination*, whether vertical, oblique, or horizontal; the *form*,

DESCRIPTION OF TATTOOS AND DISCOLORATIONS.

ANTERIOR.			POSTERIOR.			
No.	RIGHT.	LEFT.	LEFT.	RIGHT.		No.

Fac-simile of a double page from the Register of Deserters and other Delinquent Soldiers.

rectilineal, curved (inward or outward), oval, circular, undulated, or oblong; the *character*, if scar, whether recent, permanent, or transient; if mole, hairy or otherwise, etc.; and the distance of the mark from some fixed anatomical point, for example, 'Scar, from burn, one and three-fourths inches above and one inch to the right of left nipple, oblique, curved inward.'

"When numerous small scars are found on the back, from pimples, or on the fingers, from cuts, note them as 'numerous scars,' or describe the principal one and add the words 'and many others;' describe briefly tattoo marks and distortions of the finger- and toe-nails, *i.e.*, the striated or split nail of the finger, or the hypertrophied nail of the great toe.

"If, after careful search, no personal marking is found, the fact should be noted on the figure-card.

"For the purpose of securing uniformity in the description of color of eyes and hair, observe the following:

"*Color of Eyes.*—To be described as:

Blue { Light. / Dark. / Slate. } Brown { Light (or hazel). / Dark. }

Black.

"'Slate blue' takes the place in description of *gray*, which is inexact and vague.

"Black is seldom found except in negroes; the so-called black eye is, properly speaking, a dark brown.

"Malformations of, or abnormal discoloration in, the iris, and marked differences in color between the eyes should be noted.

"*Color of Hair.*—To be described as:

Blond { Light, and sometimes flax-colored. / Deep. } Red { Brick. / Sandy. / Auburn. }

Brown { Light. / Dark. } Gray { Light. / Mixed (iron). }

Raven black. White.

"Note name and organization, age in years and months, and height in inches and quarters thereof. Care should be taken in measuring for height that the occiput, the sacrum, and the heels touch the vertical rod."

To insure accuracy of description in the color of the eye, two cards are issued bearing lithographic plates of the various shades of blue and brown colors that are found in the human eye, each plate being designated by a numeral that may be used for notation on the figure-card.

Further instructions from the War Department require all officers concerned to transmit to the Surgeon-General, within twenty-four hours after the fact, a brief report of the name, company, and regiment of every soldier who deserts or is discharged the service for cause.

The figure-cards of recruits are filed immediately upon receipt, in the Bureau of Classification, in suitable boxes that are arranged alphabetically, and when the reports of men who have been eliminated from the service are received they are sent to the same place, where the work of comparison is carried on as follows:

A study of the figure-cards showed that the work could be most satisfactorily performed by using the colors of the eye, of which there are practically but two, as the initial division into sections for comparison, and that the other divisions could be best used when grouped upon a printed form in a register which consists of two volumes, one for the blue-eyed, the other for the brown-eyed men, and is divided, according to height, as follows: 64 inches and under, 64½, 65, 65½, 66, 66½, 67, 67½, 68, 68½, 69, 69½, 70, 70½, 71, 71½, and over. Each register is ruled in columns for the various regions of the body, as "anterior, posterior, right, and left," for the general divisions, with head, neck, shoulder, thorax, abdomen, groin, hip, thigh, knee, leg, ankle, foot, toes, etc., for the specific locality.

As a primary step, the report of discharge or desertion (which it should be remembered contains only the name, company, and regiment of the individual, and the date of discharge or desertion) is completed by taking from its place in the file box the figure-card that was made at the time of enlistment, and from the completed report a transcript is made on the register, the selection of volume to be used being determined by the color of eye.

Immediately upon arrival of a morning's mail, such figure-cards of recent enlistments as may have been received, are compared with the register after this manner: The color of eye indicates the volume of the register, and the height indicates the page in which search has to be made. In this latter item, an inch below and a half inch above the height recorded on the figure-card is allowed for variation or defective measurement. Each section of height is again divided, and men having tattoos are entered apart from those having no tattoos, for a deserter having tattoos is very likely to have the same when reentering the service, and a recruit coming in without tattoos is not likely to be found among those with tattoos; recruits coming in with tattoos are, however, examined over those deserters who did not have such marks, as these different devices might have been put on while at liberty.

The abbreviations used in entering descriptions of deserters are almost self-explaining, as: V. = vaccination; S. = scar; T. = tattoo; B. = birth-mark; M. = mole; S. P. = small-pox; C. P. = chicken-pox, etc.

The first comparison is for name, after which it is continued for tattoo marks, and if their peculiar design or locality give suspicion of identity, an inspection of the sectional form on the opposite page of the register is made by glancing from left to right along the line bearing the record of the individual who has the suspicious tattoo, for any further mark of identity. If there is a sufficient number of similarly located and described marks to increase the suspicion of identity, the form of physical examination and the enlistment papers are brought into requisition for comparison of signature of the recruit, and for his general history, and should this be enough to justify moral certainty of identity, the case is reported to the Adjutant-General for further action.

Should there, however, be no tattoos recorded on the figure-card that has been received, note is taken of the next prominent mark, which may be a birth-mark, a hairy mole, a scar from burn, etc., or a small permanent scar in an unusual location, such as in the popliteal space, finding which, a further and more careful search is made for other marks that may be confirmatory of identity; failing in this, any other mark or peculiarity of person is examined, such as abnormal nasal septum, prominence or not of ear; or, if nothing is found, identity fails, and the papers are placed in the files of the Bureau. The time consumed in making one of the examinations averages fifteen minutes, although in plain cases but a few minutes are required.

At the date of this paper 31,138 outline figure-cards have been received, and the number of cases reported as having left the service for cause is 5,765, of whom 4,096 were deserters and 1,669 delinquents from other causes.

Three hundred and twenty-eight cases of identity have been reported since the introduction of the outline-card system, and seven cases were reported as probably identical. The following is the result of the investigation made in the cases:

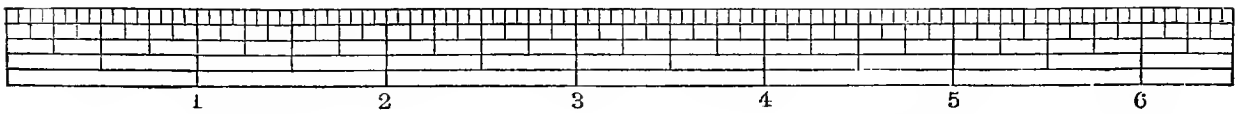
a. Identity established and final action reported by military tribunal	198
b. Reported identity and accepted by the War Department	115
c. The suspect deserted before investigation	5
d. Ex-convict; had permission to re-enlist	1
e. Insane soldier; discharged for insanity before investigation	1
f. Doubtful cases, reported as probably identical	7
g. Failures, identity not established by military tribunal	4
h. Recent cases, investigation pending	4
Total	335

a. This group of cases includes all in which identity was claimed without reservation because of the similarity

of record on the figure-cards, and was subsequently established by the proper military tribunals.

b. This group embraces cases in which the evidence of identity was conclusive, but as the suspects were out of the service, the cases were reported for correction of the enlistment papers. The Adjutant-General has accepted the identity in all of the cases.

f. These cases were reported as probably identical; although more or less prominent points of resemblance were present the discrepancies were such that no positive statements were justified, the evidence being submitted for what is was worth. In only one case was the identity absolutely disproved; in four the negative statement of the officer conducting the inquiry was accepted without further inquiry, and in the sixth case inquiry was dropped, the officer charged with it reporting that he had no funds to secure a desired photograph.



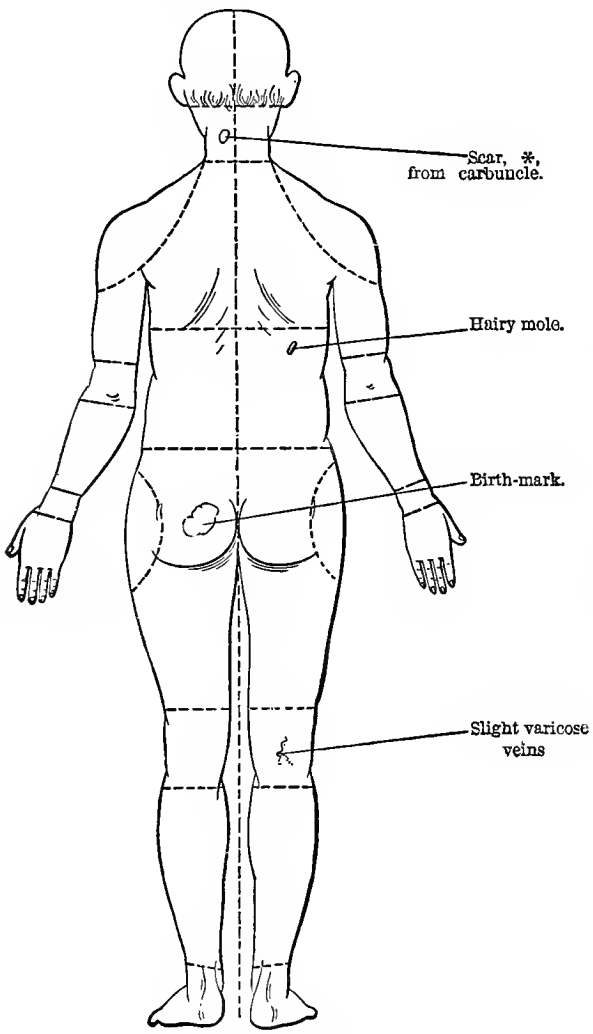


FIG. 520.

Age: 22 years 4 months.
Height: 64¾ inches.
Color of hair: Red.
Color of eyes: Slate blue.
Place of enlistment: Cleveland, Ohio.
Date of enlistment: April 5, 1890.
Prior U. S. Service?: No.
Name: John Smith.
Organization: G. S. Recruit.

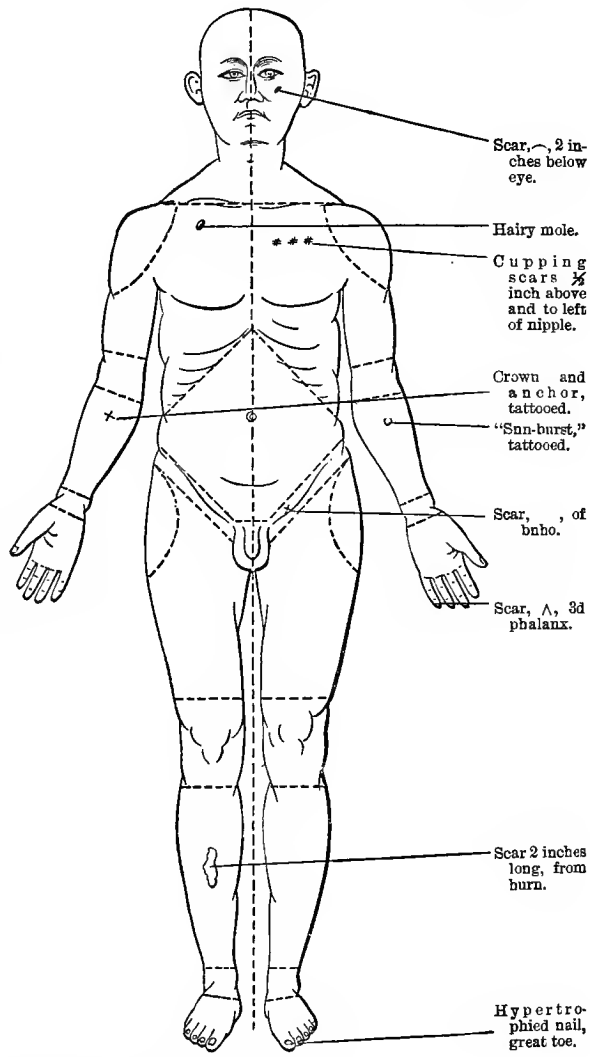

FIG. 521.

Station: Columbus Barracks, Ohio.
Date: April 10, 1892.

.....
Surgeon, U. S. Army.

c. These cases were reported as identical, but no investigation could be made because the man in each case deserted a short period (in some cases a day or two only) before or after identity was reported. After several of this class had thus succeeded in escaping, the telegraph was made use of in ordering arrests. As may be surmised, they occurred only among the earliest cases of identity.

g. Two of these cases were submitted with class *a* through error. The card record did not present sufficient evidence to warrant complete identity, and they should have been submitted with class *f*; they were failures. One case was identified by the Examining Surgeon, but was acquitted by the Court, and one case was

a failure, doubtless due to erroneous entry on the card by the recording officer.

The following is a synopsis of an interesting and somewhat complicated case:

There was submitted to the Department, October 28, 1890, a set of figure-cards indicating that one *George Howie*, who was enlisted October 10, 1890, was probably identical with *George Harrison*, who deserted August 6, 1889. Howie positively denied his identity with the deserter Harrison. His company commander, who conducted the investigation, although admitting that there was "a remarkable similarity in the two outline cards," reported that in his opinion the two persons were not identical, supporting his views with an enumeration of the discrepancies presented by the two cards. Under date of November 12, 1890, a restatement of the case was made, with recommendation that the "suspect" should be confronted with some of his former comrades, and a non-commissioned officer, who was supposed to be acquainted with Harrison, was accordingly selected for the purpose, but failed to recognize Harrison in the alleged Howie. Tracings of the signatures of Howie and Harrison were then made, and as they were strikingly similar, they were added to the evidence previously submitted, which was again referred to Howie's commanding officer, requesting further comparison. He replied: "I agree with the Surgeon-General that there can be but little doubt as to the identity of these (seemingly) two men. But still there is a doubt in my mind as to the identity." He points out the failure of the non-commissioned officer to identify the man, and remarks with reference to the striking similarity in the tattooing that he does not attach as much importance to it as it seems to warrant, from the fact that he has seen on a number of occasions as many as four men "tattooed exactly alike, as far as the location and shape of the figure was concerned." He admits that the coincidences are remarkable, and were it not for the fact "that Sergeant Cook failed to identify the man," he would have him arrested and tried for desertion. The arguments of the company commander were met, and final request was made to confront Howie with several witnesses who had known Harrison, but this was declined by the War authorities, with the following final statement:

"The best evidence that this case is a case of mistaken identity is the fact that the soldier, knowing that he was not only under suspicion, but under investigation, has remained with his company and performed his duty up to last muster, February 28, 1891."

This "best evidence" was overthrown within a few days by Howie's desertion, after ascertaining that additional evidence had been submitted connecting him with a dishonorable dismissal by sentence of a court-martial in 1887.

Charles R. Greenleaf.

PHARMACOPŒIA. Since the publication of the article on this subject in the main work (Vol. V., pp. 622–629), a number of new national pharmacopœias have been issued, while several others are in course of preparation. The labor bestowed on these recent issues has been, comparatively, much greater, and, being shared by the professions of medicine and pharmacy, the work has been much more evenly divided than has been the case in the past. A natural consequence of this is the greater recognition of these works as authorities, both for medical practice and for the decision of legal questions involving the purity of articles of food and drink, or of drugs. Their usefulness, however, can be extended still further in the future, it being only needed that a thorough weeding out of old-fashioned and antiquated notions be inaugurated at some favorable time. The increasing number of synthetic chemicals of recognized medicinal value, the discovery of more proximate principles upon which the activity of many vegetable and even some animal drugs depends, and the better understanding of the sphere of action of these agents of constant composition will eventually cause to be thrown out of the pharmacopœias a multitude of remedies, simple and compound, the reputation of which rests on empiricism, often of a very problematical character. A sudden transition from the present condition of things to the prospective purism in medicine can, however, not be expected. The transition must be gradual, due account being taken of the older generation of practitioners of medicine and pharmacy. Still, with each succeeding decennium the ratio of innovation and improvement may become more progressive, until the time be reached when the old ballast may be completely thrown overboard.

ARGENTINE REPUBLIC.—The previous commission appointed for the preparation of a national pharmacopœia having accomplished nothing, a new one was appointed in June, 1892.

AUSTRIA-HUNGARY. — After an interval of twenty years, a new Pharmacopœia Austriaca (Editio VII.) was issued in 1889, and went into effect on January 1, 1890. It contains 578 articles, 43 more than the preceding edition.

The Hungarian Pharmacopœia was revised, and appeared in its second edition in 1888, under the title: "Magyar Gyógyszerkönvy · (=) Pharmacopœia Hungarica. Második Kiadás: (=) Editio Secunda." It contains 516 articles. Both in title and in arrangement of text it is very similar to the first edition, the text being in Latin and Hungarian, on opposite pages.

The first Croatian Pharmacopœia appeared in the same year, under the title: "Hrvatsko-Slavonska Farmakopœa: Pharmacopœia Croatico-Slavonica. [8° Zagreb (= Agram), 1888]." It contains 518 articles, and is, practically, a duplicate of the Hungarian (II.), having the Slavonic and Latin text on opposite pages.

BRITISH EMPIRE.—In 1886 the General Council of Medical Education and Registration of the United Kingdom—generally designated by the shorter title: "British Medical Council"—appointed Professor John Attfield, one of the editors of the British Pharmacopœia, as "Reporter on the British Pharmacopœia to the Medical Council," the office being intended to be permanent, for the purpose of gathering up, during each year, from the current literature, whatever has a bearing upon the contents of the British Pharmacopœia, and to make suggestions for its future improvement. In accordance with this new departure, annual reports have been issued since 1887, each covering the literature of the preceding year.

In 1888 the third reprint of the British Pharmacopœia of 1885 was issued, and in December, 1890, appeared the first supplement, under the title: "Additions made in 1890 to the British Pharmacopœia of 1885," etc., which contained 44 new articles. In the preparation of this addendum the pharmaceutical profession of Great Britain was, for the first time, invited to participate, at least so far as to be asked to suggest desirable additions, or improvement of existing formulæ. It is to be hoped that, at a subsequent revision, the pharmacists will be given an opportunity of assisting the editor during the actual work of revision.

In order to prepare a uniform guide for the preparation of the most commonly used unofficial remedies, the British Pharmaceutical Conference undertook the publication of an unofficial formulary, which appeared in 1887, under the title: "Unofficinal Formulary of the British Pharmaceutical Conference." This contained 37 articles. In 1889 a supplement to this was issued, containing 9 articles. The formulary is generally designated by the abbreviation, U. F. B. P. C.

CROATIA.—See Austria-Hungary.

DENMARK.—A new Danish pharmacopœia was published in the spring of 1893, which was ordered to go into effect on August 1, 1893. The text is in Danish, only the titles of the articles being in Latin.

GERMANY.—A permanent Pharmacopœia Commission was created by Government in 1887. This body held its first session in April, 1888. In 1890 appeared the third edition of the German Pharmacopœia, under the title: "Arzneibuch für das Deutsche Reich. Dritte Ausgabe. Pharmacopœia Germanica. Editio III." Excepting the titles of the pharmacopœial articles, the text is entirely

in German, the Latin language having been abandoned in accordance with the modern views of educational authorities, which have recently been carried into practical effect by curtailing the time and degree of attention heretofore devoted to classical languages in the Latin schools and gymnasiums. This issue of the German Pharmacopœia had the advantage of a much more careful preparation than any of its predecessors, chiefly through the careful study of the more important articles on the part of the Pharmacopœia Committee of the German Pharmaceutical Association (Deutscher Apotheker Verein) under the chairmanship, first of Dr. O. Schlickum, and subsequently under that of Dr. G. Vulpius.

The example set by the United States (1886 to 1888) and Great Britain (1887), in preparing national formularies of unofficial preparations was followed by the pharmacists of Germany in 1891, when the German Pharmaceutical Association published a similar work under the rather awkward title: "Arzneimittel welche in dem Arzneibuch für das Deutsche Reich (Dritte Ausgabe; Pharmacopœia Germanica, Editio III.) nicht enthalten sind" (="Remedies which are not contained in the Arzneibuch," etc.). This contains 811 articles.

Hungary.—See Austria.

Italy.—After many delays and changes the commission charged with the preparation of a national pharmacopœia completed its labors and published the work in 1892, under the title: "Farmacopea ufficiale del Regno d'Italia" (8°, Roma). The main titles of the pharmacopœial articles, of which there are 597, are in Italian, with Latin synonyms. This pharmacopœia contains many features of importance, though some of them are of questionable utility. Thus, for instance, in the case of powerful drugs, the percentage of active principle which they contain, or may be expected to contain, is given. For instance, under belladonna it is stated that "the root and the leaves contain about 0.5 per cent. of hyoscyamine and atropine." Under jaborandi: "Contains pilocarpine (about one per cent.)," etc. Under colchicum: "The bulbs contain 0.08 to 0.20 per cent. of colchicine; the seeds 0.2 to 0.4 per cent.," etc. Yet in none of these and a number of other cases is there a process of assay given. This is, no doubt, owing to the fact that our methods for the quantitative determination of many proximate principles are not yet sufficiently reliable to be officially prescribed in a pharmacopœia. For this reason, however, it is illogical to make a demand of definite limits of alkaloidal strength in the case of any drug where no definite method of assay can be prescribed.

Japan.—The second edition of the Japanese Pharmacopœia was published in 1891, under the title: "Pharmacopœia Japonica. Editio altera. Tokyo, Anno XXIV. Meiji (1891)." It is wholly in Latin. It resembles its predecessor in general appearance and construction, but in the nomenclature of chemical substances the last German and Austrian Pharmacopœias have been followed as guides.

Netherlands.—A Government Commission for revising the pharmacopœia was appointed in 1884, and the new edition appeared in 1889, under the title: "Nederlandsche Pharmacopee. Derde Utgave (= third edition). 's Gravenhage, 1889." Excepting the titles of the official articles, the text is entirely in Dutch. This was soon followed by a Latin edition, under the title: "Pharmacopœa Neerlandica. Editio tertia. Hagæ Comitis, 1889." It was specially decreed, however, that the Dutch edition was to be considered as the official one.

In 1891 the Rotterdam Branch of the Netherlands Pharmaceutical Society (Nederlandsche Maatschappij ter Bevordering der Pharmacie) followed the lead of other countries, by issuing an unofficial formulary under the title: "Supplementum op de derde Utgave der Nederlandsche Pharmacopee. . . 's Gravenhage, 1891." It contains 573 articles.

Mexico.—The Mexican Pharmacopœia is not published by authority of the National Government, but by the Mexican Pharmaceutical Society. Two editions have so far appeared. In 1890 the Society published a supplement under the title: "Apéndice á la segunda edicion de la Nueva Farmacopea Mexicana de la Sociedad Farmacéutica de México. Escrita por la Comision Permanente de la Farmacopea." This work is a literary curiosity, teeming with blunders of fact, orthography, and nomenclature. (See review in *American Druggist*, New York, 1891, p. 291.)

Russia.—The fourth edition of the Russian Pharmacopœia was published in 1891. Like its predecessors, its text is in Russian, the titles of the articles, of which there are 808, being in Latin.

Switzerland.—The new pharmacopœia for Switzerland—Pharmacopœa Helvetica, Editio III.—has been completed and will be issued some time in the year 1893.

United States.—In May, 1890, the Decennial Convention for Revising the Pharmacopœia met at Washington, and resulted in the election of a Committee of Revision consisting of twenty-six members located in different sections of the country. Among the instructions given to this committee was, to employ the metric system of weights and measures in place of "parts by weight." At this time (June 16, 1893) the revision of the text has been completed and the work is passing through the press. A great amount of labor has been bestowed upon the new text by the members of the committee, and it is expected that it will be found to have maintained its rank among other works of this kind. It may be stated here that ninety articles, formerly official, were dismissed, and eighty-eight new ones introduced.

In 1886 the American Pharmaceutical Association undertook the publication of a National Formulary, which should provide standard formulas for the most commonly used unofficial preparations. This work was completed and published in 1888, under the title: "The National Formulary of Unofficial Preparations. First Issue. By Authority of the American Pharmaceutical Association." It contains 435 articles.

Universal Pharmacopœia.—In this place should be mentioned the work by Dr. Bruno Hirsch, of Berlin, entitled: "Universal-Pharmakopöe. Eine vergleichende Zusammenstellung der zur Zeit in Europa und Nordamerika gültigen Pharmakopöen" (= Universal Pharmacopœia. A comparative Digest of the Pharmacopœias in force at the present time in Europe and in the United States). This work contains practically the whole text of the several pharmacopœias (except that of Portugal) in such a way that the similarities and differences of the requirements of the several texts are shown at a glance in connection with each subdivision of an article. It is a work of reference indispensable for every Revision Committee in this and other countries for many years to come.

International Pharmacopœia.—The project of an international pharmacopœia does not appear to be any closer to its realization at the present time than it was five years ago. But instead of attempting the almost impossible, the advocates of uniformity in medicines appear to be willing to bring about the desired end by natural means, that is, by first causing the consolidation of the pharmacopœias of contiguous countries, particularly those in which the same language is spoken. Thus, Germany has long ago displaced the host of local pharmacopœias in existence previous to the establishment of the empire by a single national work. Italy has just done the same. The Scandinavian countries also contemplate doing this. A plan has recently been presented for the establishment of a common pharmacopœia for the American continent. This is too wide a scope to be feasible at present. But it *is* feasible to prepare a pharmacopœia for all the Spanish-speaking countries in Central and South America, provided all political differences are waived for the sake of the benefit which may accrue from the result. After some uniformity has been reached in Central and South America, it remains to be seen how much further it can be carried. It is easy to foresee that there never will be an international pharmacopœia which will replace each individual national one. The

best that can be hoped for is a work containing the description, definition, requirements of purity and strength of what may be called international remedies, single or compound, and even this cannot be introduced without risking danger from the administration of preparations the strength of which as contained in the international pharmacopœia differs from that prescribed in the national pharmacopœia of the dispenser. *Charles Rice.*

PHENACETINE. (Para-acet-phenetidine.) This well-known and popular derivative of coal tar was introduced in 1887 by Dr. O. Hinsberg and Professor A. Kast.[1] Its chemical formula is $C_6H_4OC_2H_5NHCH_3CO$. The following method is given for its preparation: para-nitro-phenol is first prepared by the action of nitric acid upon melted phenol, ortho-nitro phenol being separated by distillation, sodium para-nitro phenol is then formed by the addition of soda, and this is converted by the action of ethyl iodid into para-nitro phenetol; the latter is reduced to para-amido phenetol (para-phenetidine) which by prolonged boiling with glacial acetic acid yields para-acet phenetidine. The chemical relation of phenacetine to allied compounds will be readily understood by reference to the following formulæ:

Acetanilide, $C_6H_5{<}^{H}_{NH\ CH_3\ CO}$.

Exalgine, $C_6H_4{<}^{CH_3}_{NH\ CH_3\ CO}$.

Methacetine, $C_6H_4{<}^{OCH_3}_{NH\ CH_3\ CO}$.

Phenacetine, $C_6H_4{<}^{OC_2H_5}_{NH\ CH_3\ CO}$.

Phenocoll, $C_6H_4{<}^{OC_2H_5}_{NH\ CH_2\ NH_2\ CO}$.

Phenazone, or antipyrine, which is therapeutically allied to the above, is related only so far as all are derived from phenyl compounds; its formula is

$$C_6H_5N{<}^{CO\ CH}_{N\ CH_3\ C\ CH_3}.$$

Phenacetine forms in white, glistening, scaly crystals, without odor or taste. It is slightly soluble in cold water, 1 part in 1,500; more soluble in hot water, 1 part in 70; and freely soluble in rectified spirits, 1 part in 16; it is also soluble in glycerine. The crystals melt at 275° F. A recognized test for phenacetine is the production of a deep-red color when chromic acid is added to a cooled and filtered solution of one grain in twenty minims of hydrochloric acid diluted with ten times its volume of water. Sulphuric acid should dissolve it without color, and burned with free access of air it should leave no residue. The presence of para-phenetidine may be detected by melting forty grains of chloral hydrate in a water bath, and adding eight grains of phenacetine and well shaking; a solution takes place which is colored violet, reddish, or bluish in tint, according to the proportion of the impurity present. Another test, though less delicate, is to add eight grains of phenacetine to one and a half drachm of iodine solution, 1 in 20,000; when filtered a pure salt yields a colorless liquid; a pink tint indicates the presence of para-phenetidine. Phenacetine does not form a bromine compound as acetanilide does, and this reaction furnishes a test for the presence of the latter salt; the addition of bromine water to a saturated solution of the suspected salt, imparts a yellow color; if acetanilide is present the solution becomes turbid, if it is absent it remains clear. The presence of acetanilide, exalgine, or methacetine may be detected by adding two grains to twenty minims of concentrated hydrochloric acid; phenacetine remains undissolved, the other salts enter into solution.

Phenacetine was introduced as an analgesic and antipyretic much superior to the other similar compounds, on account of its freedom from any toxic action. It rapidly established a reputation as one of the most safe of the numerous new antipyretics, and has been very extensively employed in all febrile diseases, and for the relief of pain in all its forms. Its action is not accompanied by the numerous unfavorable symptoms that are common to the coal tar derivatives. The only undesirable effect that is occasionally caused by its use, is the onset of sweating, more or less profuse. This accompanies a rapid decline of temperature, but it is not excessive, and is not followed by any sense of prostration or depression. Although its composition is such that it may cause the alterations of the blood that are produced by exalgine, acetanilide, etc., the instances in which any such condition follows its use are extremely rare. A few cases, however, are reported in which there was paleness and coldness of the extremities, free perspiration, precordial pain, dyspnœa, shallow respiration, feeble pulse, cyanosis, and other evidences of collapse. These cases of poisoning occurred in females, and generally followed the employment of large doses; but in one case only three doses of seven grains each were given. Very large doses have been given without any ill effects. A case is reported in which sixty grains were given daily for two weeks, as an anodyne; in another case one ounce and one drachm was given during one week to a patient with neuritis, and in a case of tetanus one ounce and five drachms were given in nineteen days. During experimental research upon animals, it has been given for a prolonged period in doses equal to one and two-thirds grain per pound of body weight without producing any derangement of the system, or causing any irritation to the mucous membrane of the stomach.

The effect of the drug on the heart, and the changes in the blood-pressure that may accompany its medicinal use, appear to be uncertain. There has been comparatively little done to determine the physiological action of phenacetine, and the prevailing opinion of those who have experimented with the drug is, that there is little or no action on the heart and no alteration produced in the blood-pressure. A series of experiments on animals by Drs. Cerna and Carter[2] have led them to different conclusions, which they sum up as follows: 1. Phenacetine in moderate doses, causes a rise of the arterial pressure by acting upon the heart, and probably likewise by a stimulating influence exercised on the vaso-motor system. 2. In large amounts it causes a reduction in the pressure, which is largely of cardiac origin. 3. In small doses it increases the force of the heart by a direct action. 4. It increases the pulse-rate chiefly by cardiac stimulation, and possibly also by influencing the cardio-accelerating apparatus. 5. In large quantities, the drug reduces the number of pulsations, primarily by stimulating the cardio-inhibitory centres, and later by a depressant action on the heart. They also found that in large amounts it caused a marked quickening of the respiratory movements by a direct action on the medulla, and that where sufficient quantities were given to produce death it was due to respiratory failure.

As an antipyretic it is given in doses of eight or ten grains, every hour or every two hours. It reduces the temperature slowly and effectively; during the first and second hour there is not much influence on the fever, but in the third hour its greatest effect is manifested. The continuation of the afebrile state varies, but usually after the fourth or fifth hour the temperature begins to ascend. The fall of the temperature results chiefly from a decrease in heat-production, with a slight increase in the heat-dissipation. The slow action of the drug is thought to depend on its insolubility. In chronic febrile troubles its action is not so marked, and a tolerance of the drug appears to ensue upon its prolonged administration. When there is pain, restlessness, and insomnia accompanying the fever, the beneficial effects of the drug are most marked. A sense of ease and comfort is produced, and a calm, refreshing sleep follows. By some it has been supposed to exert a decided hypnotic action, but careful observations in melancholia and mania have not confirmed this view. In typhoid fever it has proved of great service. From five to eight grains are generally sufficient to reduce the temperature to normal in about

three hours; when it begins to rise again a second dose will prevent any hyperpyrexia for twenty-four hours. Many prefer to employ it in smaller doses frequently repeated—two grains every two or three hours and continued throughout the period of pyrexia; in this way it maintains the temperature at a low point and the fever runs a mild and uncomplicated course. In children it proves beneficial in all febrile disorders; single doses of two grains will produce a lowering of temperature, or it may be given in fractional parts of a grain every two or three hours; one-third of a grain having proved sufficient to subdue the fever and allay restlessness. During the recent epidemic of "*la grippe*" it proved very serviceable, and replaced the older antipyretics to a very great extent. In this disease the small and frequently repeated doses were of little avail, a single dose of ten or fifteen grains being generally sufficient to relieve the fever and the severe cephalalgia with which it was usually accompanied. One of its earliest applications was as an antirheumatic. It has no influence in warding off the cardiac and other visceral complications, but it reduces the fever and lessens the pain and swelling in the joints; to be of any benefit it must be employed in much larger doses than in any other febrile affection. At least fifteen or twenty grains must be given three times daily, and some state that a better effect is produced by thirty grains given twice in the day. In children five grains three or four times a day may be required. In painful affections unaccompanied by fever, and in the various forms of neuralgia, it requires to be given in the same full doses to secure a relief from suffering. A single dose of fifteen to twenty grains will prove sufficient when any benefit is to be derived, while small and frequent doses exercise very little, if any, action in controlling the pain. Phenacetine has also acquired a reputation as a remedy for whooping-cough. It is given in doses of from half a grain up to two grains every four hours, and affords rapid relief to the severe paroxysms. It is also supposed to shorten the duration of the disease.

Compared with the allied drugs, phenacetine may be said to be more pleasant and safe, but less powerful and slower in its action; and perhaps less certain, as it frequently fails to produce the desired effect.

For the purpose of testing the relative action of antipyrine, acetanilide, quinine, kairin, sodium salicylate, thallin, and phenacetine, these antipyretics were given to a tubercuIous patient under, as nearly as possible, the same conditions in regard to the height of the fever.[3] It was found that fourteen grains of phenacetine lowered the temperature more than fifteen grains of antipyrine, quinine, or kairin, and more than three and a half grains of thallin; thirty-one grains of salicylate had no effect; five grains of acetanilide acted one hour sooner and lowered the temperature a few tenths more, but the antipyretic action was not of so long duration. It was also noticed that the perspiration was not so marked as after thallin and acetanilide: there was no ringing in the ears as after sodium salicylate, no dizziness as after quinine, and no chilly sensation such as often follows acetanilide.

Dr. A. Crombie,[4] Superintendent of the Government Hospital, at Calcutta, has given a very valuable *résumé* of his observations upon the comparative value of acetanilide, antipyrine, and phenacetine, as antipyretics, in which he arrives at the following conclusions:

"First, as regards efficacy, antipyrine comes first, and there is little to choose between antifebrine and phenacetine in the doses in which I have prescribed them.

"Second, that as regards safety, the advantage lies with phenacetine. I have never seen a subnormal temperature result from the use of that drug. I have seen subnormal temperatures as the result of the use of antifebrine, but never collapse, which I have once seen follow the use of antipyrine.

"Third, as regards rapidity of action, antipyrine, probably on account of its solubility, comes first, antifebrine second, phenacetine third. The fall after the use of phenacetine is more gradual, and the minimum is not reached for three, four, or even five hours after the administration of the drug.

"Fourth, as regards duration of effect, the advantage lies with phenacetine.

"Fifth, as regards certainty of action, I would quote them in the same order as that of rapidity—antipyrine, antifebrine, phenacetine. And here let me give a warning against the use of phenacetine tabloids. They are so hard as to be practically insoluble in the stomach, or at least to be so slowly dissolved that a very small quantity of the drug enters and circulates with the blood at one time, not sufficient to affect the temperature. It should be prescribed either in powders or in lozenges, which are soft and pliable.

"Sixth, as regards inconveniences, in the climate of India phenacetine is followed by just as profuse sweating as either antifebrine or antipyrine, and this, to my mind, is the great drawback in the use of antipyretics, patients having to change their clothing once or twice in a night after the use of any of these drugs. Whether or not an antipyretic will yet be found which will be capable of safely reducing abnormal temperature without causing profuse perspiration, remains to be seen, but as yet we do not possess one." *Beaumont Small.*

PHENAZONE. "ANTIPYRINE." "ANALGESINE"

(Phenyl-dimethyl-pyrazolone). C_6H_6N, COCH, NCH_3 CCH_2. This popular antipyretic was made known to the profession by Ludwig Knorr in 1884. It is a coal-tar derivative which is prepared after a patented process, by the action of acetyl-acetic ether upon phenyl-hydrazine. It is a base somewhat analogous to ammonia, and has the property of combining with an acid or an alkali to form salts.

It occurs in colorless, scaly crystals, without odor and possessed of a somewhat bitter taste. It is readily soluble in water, alcohol, and chloroform, less so in ether, about one part in fifty. The melting point is 110° C. Ignited with free access of air it burns without residue.

Antipyrine may be detected from all other organic compounds by the action of ferric chloride; this producing a deep red color which is discharged by the addition of dilute sulphuric acid in excess. Other compounds produce various colors and differ in the effect of the sulphuric acid. The bright-red color is clearly visible in 1 to 100 solution; in 1 to 100,000 a light brown, and in 1 to 500,000 a light yellow color is produced. Nitrous acid added to a solution forms a green color, and nitric acid a yellow color which deepens to crimson on warming. Both these tests are characteristic of antipyrine. The presence of acetanilide is also detected by the melting point of the suspected salt. The two compounds melt approximately at the same temperature, but a mixture of the two reduces the melting point very decidedly, equal parts melting at 45° C. Many other distinctive tests have been proposed. In 1 to 1,000 solutions, iodine and iodide of potassium produce a reddish-brown, potassio-mercuric iodide a white, and potassio-bismuthic iodide an orange-red precipitate. In 1 to 100 acidulated solutions, Nessler's reagent, mercuric or auric chloride, and tannic acid, produce colorless or yellow precipitates; picric acid a yellow; and ferrocyanide of potassium a bluish-green precipitate.

The solubility of antipyrine and its action as an alkaloidal base, render many drugs and preparations incompatible, and not infrequently some very unsightly as well as inert mixtures are ordered by the physician. E. J. Millard and A. C. Stark[1] describe a series of experiments made for the purpose of testing the compatibility of antipyrine with the whole of the drugs and preparations of the pharmacopœia that are likely to be prescribed in combination, together with many that are unofficial. The following is the list they have prepared and the changes that are produced:

Acid., carbolic.: precipitated.

Acid. hydrocyan. dil. : yellow coloration
Acid. nitric. dil. : faint yellow coloration.
Acid. tannic. : white insoluble precipitate.
Alumen (ammonia) : deep yellow coloration and precipitate.
Amyl nitrite (acid) : green coloration.
Arsen. iodid. : precipitate.
Chloral hydras : precipitates in strong solution, no apparent action in dilute.
Cupri sulphas : solution turns green.
Dec. cinchonæ : precipitate.
Ext. cinchon. liq. : precipitate.
Ferri sulph. : brownish-yellow color and precipitate.
Glycer. ac. carbol. . precipitate.
Glycer. ac. tannic. : precipitate.
Hydrarg. perchl. : precipitate.
Infus. catechu conc. : precipitate.
Infus. cinchon. acid. : precipitate.
Infus. rosæ acid. : precipitate.
Infus. uvæ ursi : precipitate.
Liq. arsen. et hyd. iod. : precipitate.
Liq. ferri perchlor. : }
Liq. ferri pernit. : } blood-red coloration.
Liq. ferri persulph. : }
Liq. pot. permang. . reduction quickly takes place.
Sodii salicylas : liquefies.
Spts. ætheris nit. (acid) : green coloration.
Syr. ferri iodid. : reddish-brown coloration.
Tinc. catechu : precipitate.
Tinc. cinchonæ : precipitate.
Tinc. cinchon. co. : precipitate.
Tinc. ferri perchl. : red coloration.
Tinc. gallæ: precipitate.
Tinc. hamamelid. : precipitate.
Tinc. iodi. : precipitate.
Tinc. kino : precipitate.
Tinc. laricis : precipitate.
Tinc. rhei : precipitate.

It was found that with dilute acids no change took place, as with sulphuric, hydrochloric, nitric, and phosphoric acids, soluble salts were formed. The changes that take place with amyl nitrite and nitrous ether only occur when the preparations are acid and contain free nitrous acid, but as this is generally present under ordinary circumstances, these compounds should never be prescribed with antipyrine. Calomel is considered to form a toxic compound when combined with antipyrine, but these observers were unable to notice any change, and mercuric chloride could not be detected in the mixture. Sodium bicarbonate, when triturated with antipyrine, causes a decomposition and disengages the odor of ether. Many substances combine with antipyrine to form stable and definite chemical compounds. Some of them have proved to possess important therapeutic properties and their number is constantly being increased. The most important of these are iodopyrine, salipyrine, and hypnal (*q. v.*). *Naphto-pyrine* is formed when antipyrine is triturated for a length of time with beta-naphthol, one part of the latter with two parts of the former. It assumes the character of a tough mass which gradually forms into crystals when kept for a length of time. It is insoluble in water, soluble in alcohol and ether. A more recent method of preparing the drug is by dissolving one hundred and fifty grammes of naphthol in ninety per cent. alcohol, and adding to it gradually one hundred and ninety grammes of antipyrine dissolved in the smallest possible quantity of water. The mixture is to be constantly stirred, and in a few minutes it becomes clouded and then clear ; the pure crystals being deposited.

Antipyrine benzoate is formed by the addition of antipyrine to a boiling aqueous solution of benzoic acid. It is slightly soluble in cold and boiling water, but very soluble in alcohol and ether. It has a pungent taste and a slight odor of benzoic acid. A *citrate* and *picrate* may be prepared in the same way.

Pheno-pyrine is prepared by mixing equal parts of crystalline phenol and antipyrine. It forms an oily liquid, free from color, insoluble in cold and sparingly soluble in hot water.

Pyrogallo-pyrine is obtained by the interaction of pyrogallol and antipyrine in substance or in solutions. It is a crystalline substance, sparingly soluble in hot or cold water, but soluble in alcohol and ether.

Resopyrine results from the interaction of solution of resorcine and antipyrine ; an oily mass is formed which solidifies into a hard, white, opaque body. From an alcoholic solution it forms in crystals. It is not soluble in water, but soluble in alcohol, ether, and chloroform. All these compounds are of recent origin, and their properties have not yet been studied ; they are introduced to secure the combined action of their constituents and are yet under observation.

The physiological effect of antipyrine has received more attention than many of the later derivatives of the same character ; but the manner in which it subdues pain is as yet uncertain. In medium doses it is found that antipyrine depresses the reflex functions of the cord ; larger doses cause convulsions, and these are followed by paralysis. The primary depression is considered to be due to the stimulation of the inhibitory muscular tracts ; a continued irritation exhausts the inhibitory mechanism, and in consequence convulsions follow and ultimately complete exhaustion and paralysis. The train of symptoms that follow the administration of a fatal dose to animals is very similar in all cases.[2] There is generally marked salivation and lachrymation very quickly following the dose, crying and other signs of distress, and in a short time ataxia. This is followed by a convulsive stage, during which spontaneous convulsions are frequent, and are easily caused by flashes of light, clapping of hands, etc. ; following this, paralysis, insensibility, and death. Respiration and the heart are greatly hurried, and death occurs during a convulsion or from paralysis of respiration. The heart generally continues to beat for some time, and is finally arrested in diastole.

Upon the sensory nerves, antipyrine acts as an anodyne both when administered internally or when locally applied. This effect is early manifested, and before the convulsive stage begins it has been shown that animals can be operated upon without causing any pain. The muscular sense is also lost early, the signs of ataxia being one of the first symptoms noticed and one of the last to pass off ; the special senses are at first rendered more sensitive, but this is quickly overcome and complete anæsthesia produced.

The antipyretic properties are considered due to the action of the drug on the heat centres. Some experimenters state that the decrease in the production of heat is greater than the dissipation, while others are of an opposite opinion ; all, however, concede that both factors exert their influence, and owing to their combined action the reduction of temperature is rapid and decided

Antipyrine exerts a very decided action upon the respiration. Even in small doses it has been known to greatly accelerate the number of respirations, and in all cases in which toxic doses are given the rapidity is excessive, and, as a fatal termination approaches, the expirations become spasmodic in character. This has been shown not to be influenced by the section of the vagus nerves, and is assumed to be due to a direct action on the respiratory centre in the medulla oblongata.

In moderate doses very little effect is produced on the circulation, but in large doses it weakens the heart and causes depression and collapse. Drs. Cerna and Carter[3] formulate the following conclusions, which, in general, coincide with the work of previous observers : (1) In small and moderate amounts it produces a rise of the arterial pressure, this stimulating effect being due to an action on the heart. (2) A lowering of the pressure by large and toxic doses is due similarly to a depressant action of the drug upon the cardiac organ. The remedy does not appear to affect the vaso-motor system. (3) Antipyrine causes an increase in the pulse-rate through paralysis of the cardio-inhibitory centres. The secondary decrease in the number of pulsations is of a purely cardiac origin, the drug exercising a depressant effect upon the heart itself.

Upon the blood there is no effect when moderate doses

are administered; in large quantities, however, it produces a chocolate coloration of the blood which is due to the alteration of the hæmoglobin into methæmoglobin. There is no alteration of the corpuscles caused by the drug itself, but ultimately its administration may lead to a diminution in number from the exhaustion and debility produced.

In many instances antipyrine exerts an irritant action on the stomach and causes nausea and vomiting. Another objection to its employment is the copious perspiration that is frequently produced, and which generally accompanies a rapid reduction of temperature. A rash of the character of urticaria, in some cases described as resembling measles and scarlatina, is caused in some patients. It generally follows the use of the drug for a length of time, but in many instances a single small dose has had this effect. The toxic symptoms produced when the drug has been given in very large doses are convulsive in character, and in accord with the symptoms observed in experimental research upon animals. In lesser quantities, and often in ordinary doses, very unfavorable symptoms occur, the result of a depressant action. Collapse of the most alarming character sometimes follows ten- and fifteen-grain doses, and this is often accompanied by cyanosis, and swelling of the eyelids and extremities. The milder symptoms of a toxic action are a rapid and weakened heart, shallow respiration, dyspnœa, oppression in the chest and in the head, giddiness, vertigo, numbness of the surface, irritation of the mucous membranes and skin, and many other symptoms indicating a depression of the circulation and nervous system. This undesirable action is the one great drawback of what is undoubtedly the most efficient antipyretic and analgesic compound that has yet been produced. To this is to be ascribed its decreased employment, as the frequent onset of alarming symptoms, often as sudden as they are unexpected, has caused the profession to avoid its employment in many cases in which it undoubtedly would prove of service. A careful consideration of cases in which it is given will generally enable one to avoid these dangers. It is advised to have caution in cases of cardiac debility and whenever the respiratory organs or kidneys are interfered with. The remedy must also be cautiously given to the aged.

Antipyrine is rapidly absorbed, its effects are quickly produced; its elimination from the system begins within a short time after its administration, and it is entirely removed within comparatively a few hours. In children it has been noticed that there is apparently a tolerance of the drug, as very large doses may be given without producing ill effects. That this might be due to a rapid elimination led to a series of observations,[4] which led to very interesting results. The urine of children, adults, and aged, to whom eight grains were administered, was systematically examined to determine the first appearance of the drug and the length of time it continued to be excreted. It was found that with all the subjects excretion began within fifty minutes, and within an hour the drug was present in abundance. The excretion, however, was most rapid in the children. With them it could not be detected after fifteen or twenty hours, with adults it was present for twenty-four or thirty hours, and with the aged its excretion was still more slow. When the dose was increased it was found that its first appearance in the urine was not changed, but its elimination was much prolonged.

When antipyrine was introduced as an antipyretic the dose recommended was thirty grains in a single dose, which was to be repeated in four hours if the pyrexia was present, and a third dose of fifteen grains was to be given in another four hours if there were any signs of a rising temperature. This medication produced a decided reduction in the fever, and maintained a condition of apyrexia for twenty-four or forty-eight hours; it was, unfortunately, often accompanied by the profuse sweating and signs of collapse, and was soon abandoned. It is now given in doses of ten to fifteen grains, which may be repeated at short intervals if no effect is produced. The fall of temperature generally begins in from half an hour to one hour, and the lowered temperature is maintained for several hours. In some instances the fall is very rapid, a decline from 103° to 96° F. taking place. Sometimes it is necessary to repeat the dose very frequently before any effect is produced, it, apparently, being necessary to saturate the system before freedom from fever is secured. In typhoid fever, and in all febrile disorders in which there is a periodic rise and fall of temperature, the time of its administration should be observed, as its action is much more marked when it coincides with the decline of the fever. In typhoid fever it is rarely employed as a mode of treatment by the continuous administration of the drug; it is only considered of value as a means of reducing hyperpyrexia. Its use in tubercular troubles is not looked upon with much favor, on account of the perspiration that is caused. It has been suggested to combine atropine with it as a means of counteracting this effect. In rheumatic fever it has been advocated by many as a remedy superior to the salicylate; in these cases it is given in fifteen- or twenty-grain doses five or six times a day. In many instances it has secured relief from pain when salicylate of soda has failed, but it has not proved itself equal to the older remedy in the treatment of rheumatism in any form when accompanied by fever.

Although introduced as an antipyretic, antipyrine was soon found to possess very decided analgesic and anodyne properties, and the latter application of the drug has almost eclipsed its earlier use. In all forms of pain of a neurotic origin, or in nervous diseases accompanied by pain, it has proved itself of especial value. It has been used with success in neuralgia, migraine, sciatica, and lumbago, in the pains of tabes dorsalis, in the pains of angina, and in those arising from aneurism. It has been found to replace morphine in renal colic and asthma, and even proved itself superior, as it in no way deranged the secretion. It has been used in all conditions in which the hypodermic use of morphine is generally resorted to, and has been found a very efficient substitute in the greater number of cases. As a remedy for headaches of a nervous origin it is very beneficial. In the forms peculiar to growing children, and in those accompanying anæmia and debility, it has been recommended by Germain Sée, who employed it in a large number of cases with marked success. The same observer also considers it of value in pain of a rheumatic character unaccompanied by fever. Although inferior to the salicylates in the febrile forms, he considers it decidedly superior to all other drugs when there is no fever. In the pains of dysmenorrhœa and other pelvic disorders it has also been employed with success. Its use in such cases is indicated when the suffering is of a nervous character, as the drug exerts no influence on the uterine contractions and fails to relieve the pains that arise from the efforts of the uterus to expel its contents. In obstetrical practice it has allayed much of the suffering that accompanies labor. Its effect resembles that of chloral. In the first stage, in primiparas and in neurotic patients, it lessens the rigidity of the os and allays the painful spasmodic action. In tedious labor it lessens the exaggerated nervous pain which often in a reflex manner interferes with the efficiency of the uterine contractions. It is useless for the pain of the second stage, which is mechanical in its character. For the after-pains, due to the expulsion of clots, it is without effect, but in those that are of a grinding or neuralgic character it affords marked relief. The employment of the drug does not in any way increase the tendency of post-partum hæmorrhage. It exercises no ecbolic action, and has proved of service in allaying the pains and checking the progress of threatened abortion. It has been recommended in cases in which it is desired to reduce the secretion of milk. Cases are reported in which doses of eight grains lessened the amount within a day and checked it altogether in three days. Its action is not always so effective, as it frequently fails to secure the desired result. As it is not excreted with the milk it may be safely given without affecting the child.

The action of antipyrine on the spinal cord and nerve-

centres has led to its employment in many diseases of a neurotic character. In chorea it has proved useful, both in cases traceable to rheumatism and in those in which there was no such history. In a report[5] of sixty cases in which it was used, it was found to benefit two-thirds, diminishing the severity of the attack and shortening its duration. Recurrence, however, was noticed in three-fifths of the cases. It was found necessary to give large doses, from three to six grammes daily being required. This was found to be well tolerated for several weeks, and serious symptoms of poisoning were never noticed. Antipyrine was suggested as a remedy for pertussis by Sonnenberger, in 1887, and it has been used for this purpose to a very great extent, with varying results. The dose should be from two grains upward, according to the age of the child. One and one-half grain for each year has been advised; for infants of a few months of age one-half to three-quarter grain is sufficient. In many of the cases reported remarkable effects have been announced, the disease having been cut short in a few days. This drug has also proved of service for enuresis, when of nervous origin and due to irritability of the bladder. It has also been employed in epilepsy, but not with encouraging results. From time to time cases have been reported of diabetes that have been successfully treated with antipyrine. The quantity given has ranged from two grammes to six grammes daily. In some instances the excretion of sugar was wholly checked; in the majority it was lessened in quantity and the patient relieved of all troublesome symptoms. The most marked effects were noticed in nervous patients and when the polyuria was excessive. The diet must not be neglected.

Antipyrine possesses a decided antiseptic action, and it has been suggested that this should be utilized both by internal administration and as a local application. It has been shown that a two and a half per cent. solution prevents the development of the bacillus of diphtheria in various cultures, and a five per cent. solution applied to a culture containing the bacillus destroyed it in twenty-four hours. It has also been found to exert a powerful neutralizing action on the toxins of diphtheria. Applications to the throat and the internal administration are advocated in this disease, but there has not yet been any evidences of its beneficial effects.

In stomachic disorders and diarrhœas of children it has been employed on account of its effect in checking fermentation. It is given in doses ranging from one-half to one or two grains.

The local application has proved of decided value as an astringent and anæsthetic remedy in various troubles of the nose, throat, and larynx; a solution of the strength of about four per cent., used as a spray or painted directly on the mucous membrane, allays the congestion and lessens the sensibility and irritability of the part. It at first causes a sense of heat and smarting, but this rapidly passes away and is followed by ease and comfort, and freedom from all the painful sensations that may have accompanied the inflamed condition. The sensitiveness of the nasal membrane is more marked than that of the pharynx, and an application of cocaine is often required before the antipyrine can be applied; in such cases it is advisable to begin with a one per cent. solution. The powdered drug, or concentrated solutions, have been found to exert an anæsthetic and very astringent action, and have been used for the treatment of tubercular disease and other painful affections, and in conditions where there is a reflex element present. When applied in these concentrated solutions the anæsthesia is complete, and lasts for one or two hours. It may be applied as a spray, or by means of cotton wrapped around a probe, or the impalpable powder may be blown upon the mucous membrane. The burning sensation produced at first is rapidly overcome and is followed by comfort and freedom from pain.

Antipyrine has also been used in the treatment of certain forms of eye disease. Weak solutions of from one to three per cent. have been used with advantage in simple acute or chronic conjunctivitis. Under the influence of three or four washings a day, the secretion diminishes and a cure is rapidly effected. The solution at first causes a sensation of burning, which may be painful, but this lasts only a few moments and is followed by relief from all distress. Antipyrine[6] has recently been used to replace jequirity in the treatment of scrofulous pannus which has resisted other methods. The eye is to be rendered anæsthetic with cocaine, and a thin layer of antipyrine is deposited on the cornea with a brush, or by means of an insufflator. In spite of the cocaine the patient complains of pain and burning, and there is more or less lachrymation. When this reaction subsides the eyeball is gently massaged through the closed lid. The inflammation that arises varies in intensity, and from one to several days must elapse before repeating the process. The contra-indications to this treatment are the presence of corneal ulcerations and phlyctenular keratitis. The most suitable cases are those in which there is extensive proliferation of the blood-vessels.

A very important property of antipyrine is its power of controlling hæmorrhage. When placed in contact with blood at its normal temperature it thickens and condenses it without causing coagulation. When a concentrated solution or the powdered drug is applied to a mucous membrane it causes an anæmia more or less marked, according to the strength of the solution. When applied to an animal's mesentery the blood grows darker in color, the circulation becomes slow and ultimately ceases, and the parts appear almost bloodless after the application of a fifty per cent. solution. This styptic action may be secured by applying a plug of cotton saturated with a fifty per cent. solution to the bleeding surface, or the powdered drug may be used. This action has been confirmed in numerous cases of epistaxis, bleeding tonsils, after the extraction of teeth, and even in cases of uterine hæmorrhage. In many instances it has been found that a ten per cent. solution was sufficient in ordinary hæmorrhage from mucous membranes. In hæmoptysis of phthisis its internal administration was thought to prove beneficial, but the large quantities required to produce this effect were accompanied by dangerous symptoms.

To secure the full benefit of antipyrine as an anodyne, and upon the nervous system, it requires to be given in doses of fifteen to twenty grains, and repeated hourly until the desired effect is obtained, or until sixty to ninety grains have been given. This quantity has been maintained for a prolonged period without any ill effects, and to children much greater quantities in comparison have been given. It is generally administered in solution, and it is considered advisable to combine it with alcohol, ammonia, or some diffusible stimulant to counteract the tendency to depress the heart. The hypodermic injections have been advocated when it is desired to secure a local anodyne action. The effect is noticed in ten or fifteen minutes, and lasts for six or eight hours. The usual dose is about four grains in ten minims of water, and when the painful area is great a number of injections are required. Cocaine often has to be added, as much pain is sometimes experienced. This method of administering the drug is not without its dangers, as it has produced gangrene of the toes when injected for painful affections of the foot. When the stomach is irritable and rebels against antipyrine, or when a local action on the pelvic organs is wished for, it may be given as an enema: antipyrine, 10 to 20 grains; tinc. opii, 5 minims; aquæ, 4 ounces. It may also be prepared as a suppository where such can be used with convenience. *Beaumont Small.*

PHENOCOLL. (Amido-acet-para-phenetidine.) During the past few years our knowledge of the chemistry of modern antipyretics has so far advanced that new synthetical remedies are now produced, the therapeutic properties of which have been carefully considered before-

hand. Such an one has been prepared by German manufacturers, and introduced under the name of phenocoll. It is said to be an antipyretic, possessed of all the favorable qualities of the older compounds, and devoid of any of their undesirable effects. Of the numerous antipyretics that have been discovered, only acetanilide, phenazone, and phenacetine have been received with any favor, and each one has its objectionable quality. To remove them has been the aim of the chemist, and numerous experiments have been made by rearranging the groups of molecules, or introducing new groups, with the hope of forming such a compound as phenocoll claims to be. Antipyrine and phenacetine appeared the most suitable for experimental work, and the endeavor has been, on the one hand to render the former less toxic, and on the other hand to increase the solubility of phenacetine and make its action more rapid. The comparative harmlessness of phenacetine is believed to be dependent, not alone upon its insolubility, but also upon the presence of the oxyethyl group. Hence it was suggested that the toxicity of antipyrine might be diminished by the introduction of this, or a similar group, into its composition. This, however, has not proved a success as yet. The experiments with phenacetine were more successful, and the subject under consideration is the result of the work in this direction. Very many experiments were made with a variety of groups of molecules, but generally when the solubility was increased the antipyretic action was sacrificed or some undesirable effect introduced. The object was at length attained by replacing in phenacetine one hydrogen atom of the acetyl group by the amido group NH_2. The preparation is effected by the interaction of phenetidine (vide phenacetine) and glycocoll or amido-acetic acid. The following equation expresses the reaction that occurs :

$$C_6H_4\ OC_2H_5\ NH_2 + CH_2\ NH_2\ CO_2H = C_6H_4\ OC_2H_5\ NH\ COCH_2\ NH_2 + H_2O.$$

Phenocoll, the base, forms in white acicular crystals which have a tendency to mat themselves together. It is readily soluble in alcohol and warm water, but only slightly in chloroform, ether, and cold water. Dilute caustic alkalies, or dilute acids when cold, have no power to split up the compound, but by prolonged boiling it is resolved into its constituents. The most important characteristic of this compound is its power of combining with acids and the formation of soluble salts.

The *hydrochloride of phenocoll* is the salt generally employed, but salts have also been formed with other acids. The *acetate* is soluble in two and a half parts of water, and is more suitable for subcutaneous use, besides being milder in taste than the hydrochloride. The *carbonate* is a bulky, almost tasteless powder, not very soluble in water, but readily dissolved by weak acids. The *salicylate* occurs in long needles, it has a sweetish and not disagreeable taste, and is supposed to add some of the therapeutic properties of salicylic acid to phenocoll.

Phenocoll hydrochloride is a white, minutely crystalline powder, with a bitter, saline, but not disagreeable, taste. It is soluble in cold water, about one part in sixteen, forming a neutral, stable solution. It is still more soluble in hot water and in alcohol. The following tests are given for its purity. Half a gramme should dissolve and form a clear solution in 15 c.c. of water ; the solution should not turn litmus paper blue. Solution of ferric chloride should produce in the solution only the faint yellow color of iron salts, but not a red coloration even upon heating. Heated to 60° C., and treated with a few drops of solution of sodium carbonate, the aqueous solution should not give off the odor of ammonia. With a few drops of solution of caustic soda, the phenocoll base should be thrown down as a white crystalline mass. Burnt on platinum it should not leave any residue.

The superiority claimed for it over other antipyretics, lies not only in its greater solubility and more rapid action, but also in its perfect harmlessness. Professor Kobert states that experiments have demonstrated that it does not produce any change in the character of the blood, and very large doses have been given to animals without any deleterious effects. The result of experiments by Dr. Isaac Ott, however, shows that in very large quantities it produces the same effects as phenacetine and similar compounds. He reports : 1, that upon frogs it produces a general paralysis, due to an action upon the cerebro-spinal axis ; 2, upon rabbits it produces a cyanotic condition of the ears, and reduces the force and frequency of the heart ; 3, it kills through an action upon the centre of respiration.

That it may exercise a toxic action when administered for its therapeutic action, is also evident from a case reported by Dr. Herzog, in which severe symptoms of dyspnœa, cyanosis, and heart-weakness were produced in an emaciated consumptive patient. When administered for medicinal purposes, it produces a rapid and marked diminution of temperature without any corresponding depression of the system. Fifteen grains are stated to be equal to twenty or thirty of antipyrine, or twelve or fifteen of phenacetine. As an antipyretic it is recommended to be given in doses of eight grains, frequently repeated, in some cases every hour, until a lowering of temperature is noticed ; or it may be given in fifteen-grain doses, repeated once or twice a day. As much as seventy-five grains have been required in some instances to maintain a condition of apyrexia. In rheumatic fever it reqnires to be given in the full doses of fifteen grains ; from the report of cases treated it promises to be a remedy of some value, the pain and swelling of the joints is relieved with the lowering of temperature, and in a few days the disease is apparently under control. In addition to its use in the many forms of febrile disease, it has been found to be of service in malarial fever. Dr. Peter Albertoni was the first to call attention to its anti-periodic action at a meeting of the Bologna Medical Society, December, 1891. He first corroborated the statements regarding its therapeutic effects in fever and its freedom from injurious action, and then with the co-operation of other physicians residing in malarious districts, employed it in malarial fevers of all types. It was used in thirty-four cases, with a permanent success in twenty-four, doubtful results in five, and failure in the other five. It was given in fifteen-grain doses, in powder, six or seven hours before the expected paroxysm Very recently Dr. F. Cervello, of Palermo, reports its use in eighteen cases of quotidian, tertian, and erratic ague, in which fifteen were cured. He states that it should be given in twenty- to twenty-five-grain doses, repeated twice or three times at intervals of two hours, in such a way that the last dose shall be taken about two hours before the beginning of the attack. He considers that it is superior to quinine in many cases, particularly in the malignant forms of malaria, on account of its rapid absorption and powerful antipyretic action.

The antipyretic action of the drug is noticed within an hour, and the lowest temperature is reached within two or three hours. The effect is rapidly overcome and the rise in temperature takes place rapidly. It is excreted by the kidneys, and within twenty-four hours of its administration no trace can be detected in the urine. During its employment, the urine has been noticed to acquire a dark color, but no albumin is present and the kidneys are not in any way injured. The sweating, that often occurs, is most severe in those troubled with night-sweats, and in these cases may be overcome by the simultaneous administration of $\frac{1}{100}$ or $\frac{1}{60}$ grain of atropine. The reaccess of fever in these cases is often accompanied by more or less shivering and chilliness.

The investigations and clinical reports upon the action of this new remedy have been chiefly made in Germany by Hertel, Jacobi, Herzog, and Cohnheim, but Drs. Cerna and Carter, of Philadelphia, have done some very thorough experimental work, to determine the comparative action of antipyrine, phenacetine, and phenocoll. They consider that in ordinary medicinal doses phenocoll exercises a slightly stimulant action upon the circulation, and when it causes a depressant action, it does so in excessive amounts only. The following are their conclusions regarding its action on the heart and circulation :

1. Phenocoll, in ordinary amounts, has practically no effect upon the circulation.

2. Large doses diminish the blood-pressure by influencing the heart.

3. Phenocoll reduces the pulse-rate by stimulating the cardio-inhibitory centres. It then increases the rapidity of the pulse by paralyzing said centres. The final diminution is of cardiac origin.

4. Upon the blood itself phenocoll has no action.

As to the relative action of the three antipyretics that were experimented with, they sum all as follows :

1. Antipyrine, phenacetine, and phenocoll all fail to produce any effect on the heat functions of the normal animal.

2. Antipyrine produces a decided fall of temperature in the first hour after its administration in the fevered animal. This reduction is due to a great increase in heat-dissipation, together with a fall in the heat-production.

3. Phenacetine, both in septic and albumose fevers, produces a very slight fall of temperature during the first and second hours after its ingestion by the stomach, but the greatest reduction occurs the third hour after its ingestion. The fall of temperature results chiefly from a decrease in heat-production, with a slight increase in the heat-dissipation. The increase in dissipation is not as great as with antipyrine. Probably the delayed action of the drug depends on its insolublity.

4. Phenocoll causes in fever a very decided fall in temperature, which occurs the first hour after the administration of the drug by the stomach. This reduction is the result of an enormous diminution of heat-production, without any alteration of heat-dissipation.

Phenocoll has not been much employed in this country, and reports of its use are very meagre. The reports which have appeared are generally in its favor, but a few are not so enthusiastic over its properties ; they have found its action very rapid and evanescent, and the sweating that often accompanies its action makes its effects much more uncomfortable than those of phenacetine. The drug requires to be more studied and its unfavorable effects carefully considered, before its exact position as a remedial agent is secured. *Beaumont Small.*

PHENOSALYL. This compound antiseptic has received some attention from the fact that it is the result of a series of experiments upon the various antiseptics by Dr. de Christmas, in the Pasteur Institute, Paris. This gentleman has given a great deal of attention to the combining of well-known antiseptics for the purpose of increasing their germicidal properties. He has shown that when certain antiseptics are associated together in one and the same solution, the microbicide power is greater than the sum of the solutions of each acting separately. Among the most efficient of these combinations he gives the following :

Benzoic acid	1 part.
Carbolic acid	8 parts.
Zinc chloride	1 part.

and

Carbolic acid	8 parts.
Benzoic acid	1 part.
Oxalic acid	1 part.

or

Salicylic acid	1 part.
Carbolic acid	9 parts.

A one to one hundred solution of these mixtures kills, it is claimed, the staphylococcus aureus in thirty seconds ; the bacillus anthracis, bacillus pyocyaneus, and the bacillus of Eberth in one minute.

A still more powerful mixture was prepared by combining

Carbolic acid	12 parts.
Salicylic acid	1½ part.
Peppermint oil	1 part.

More recently he has constructed the preparation to which he has given the name phenosalyl, and this he considers the most efficient antiseptic that he has formed, its action on the various bacteria being exceeded only by sublimate. It has the following composition :

Carbolic acid	90 parts.
Salicylic acid	10 parts.
Lactic acid	20 parts.
Menthol	1 part.

The three acids are heated up to the point of liquefaction, when the menthol is added. It is very soluble in glycerine, and in water to the extent of four per cent.
Beaumont Small.

PHENYLHYDRAZINE. This powerful reducing agent has been employed as a very delicate test for the presence of sugar in urine. It was discovered by Emil Fischer, and may be prepared by reducing diazo-benzine chloride by means of the action of hydrochloric acid and tin. Its chemical formula is C_6H_6NH.

The application of this substance as a test for sugar was introduced by Professor Fischer, but a modification of his method, proposed by Bond and Ultzman (*Medical News*, 1887, 146), is that which is followed for the detection of sugar in the urine. This is applied as follows : in fifteen cubic centimetres of urine in an eight-inch test-tube, dissolve by agitation one gramme of phenyl-hydrazine hydrochlorate and two grammes of sodic acetate. Gently raise to the boiling point, which is to be maintained for half a minute, then set aside for a period varying from a quarter of an hour to twenty-four hours, according to the amount of glucose suspected. The sediment is to be examined with a ×200 or ×300 lens. The phenylglucosazon will be recognized as sheaves, sprays, or stars of delicate yellow, needle-like crystals, very similar to tyrosin excepting in color, the latter always being white. The essential feature of the crystals is the delicate acicular form. The advantages claimed for this test are : 1. Normal urine does not respond to the test. 2. It will detect one-fortieth per cent. of diabetic sugar. 3. Other substances (save albumin, which must first be removed if in any amount) do not disturb its sensitiveness. 4. Alkaline or acid, cloudy or clear, urine may be used. 5. If typical crystals are found, the proof of the presence of sugar is absolute. 6. It requires no special skill to prepare and examine the specimen. When the phenylhydrazine is in excess, various-sized reddish and yellowish globules are present in the field, and these at times have short acicular offshots which have no diagnostic significance.

This is probably the most delicate and trustworthy test we possess for the qualitative examination for sugar, as no other known substance is capable of detecting less than one part in four thousand, which is possible by this reagent.

Phenyl-hydrazine enters into the formation of many antipyretic compounds, notably antipyrine and hydracetine (*q. v.*)

Phenyl-hydrazine levulinic acid, under the registered title of *antithermin*, has been used as an antipyretic in doses of five grains. It occurs in white crystals, insoluble in water, slightly soluble in alcohol. It is but little used, as its action is uncertain, and not so reliable nor so safe as that of antipyrine and other similar preparations.
Beaumont Small.

PHLORIDZIN. A glucoside obtained from the root-bark of the apple, pear, cherry, and other fruit-trees. Its chemical constitution is $C_{21}H_{24}O_{10}$, $2H_2O$. It forms in fine, colorless, silky needles, soluble only in one thousand parts of cold water, but freely soluble in boiling water. It is only slightly soluble in alcohol. It melts at a temperature of 222° F., but becomes solid again at 226° F., and melts a second time at 335° F. Phloridzin is very similar to salicin, and heated with potash it yields phloretic acid, which is homologous with salicylic and anisic acids.

It has been employed as an antipyretic in doses of fifteen to thirty grains, but is not now used.

Phloridzin is now utilized in physiological research, as it has been found to induce artificial diabetes. When given to the extent of eight grains per pound of body weight it causes an excretion of sugar which continues for twenty-four or thirty hours. It sometimes produces diarrhœa, but no other ill effect has been detected.

Beaumont Small.

PHOTOXYLIN. A nitro-cellulose, similar to collodion or pyroxylin, but prepared from wood-wool.

A three to five per cent. solution in equal parts of alcohol and ether is recommended to replace collodion in plastic surgery and other conditions in which such an application is suggested. The solution forms a thick liquid, which on evaporation leaves a firm, dense film, which is stronger than that of collodion.

Beaumont Small.

PICHI. The Chilian name of *Fabiana imbricata*, a member of the order Solanaceæ, indigenous to South America. It is very common in Chili and grows upon high, dry hills, and in appearance greatly resembles the "heather" in appearance. The broadly ovate, thick leaves, about a line long, are densely crowded upon the small branches, and whitened at their bases and edges by a profuse deposit of resinous matter. The branches bear a single large white flower in the second year. "The calyx is free, but closely investing the ovary, to which it adheres by the resinous exudation; it is short and open bell-shaped. The corolla is persistent and is borne on an orange-colored disk one-half inch long; it closely invests the ovary, and, slightly contracting above, it becomes funnel-shaped. Stamens five, unequal, included, the thread-shaped filaments inserted into the corolla at its constricted portion. Anthers short, two-celled, opening longitudinally. Pistil bicarpellary, the edges of the carpels turned in to meet a central column which bears the numerous pendulous ovules. Style slender, equalling the corolla and bearing a slightly two-lobed stigma. Fruit an oblong-ovoid, light brown, crustaceous capsule, two and a half lines long. Seeds about four, one-half a line long, flattened, oblong, brown, with a slight tubercular, roughened, crustaceous testa, the embryo curved, with fleshy albumin." "The resin is a striking peculiarity of the plant. It exists to some extent in the wood of the smaller branches, and is detected in the older wood. The bark abounds in the resin; it is ashy-gray, and finely roughened by minute, short, sharp, thickly-set longitudinal ridges, and minute gland-like protuberances, both of which exhibit, under the lens, a peculiar resinous structure."

Various analyses of the plant have been made, but without any very satisfactory results. An alkaloid, *fabianine*, has been described, but its identity is uncertain; the medicinal properties are more generally ascribed to a florescent glucosidal principle. It also contains resins and an essential oil, with an odor said to resemble vanilla.

Pichi was introduced as a remedy for the various disorders of the urinary apparatus, by Professor H. H. Rusby (*Therapeutic Gazette*, 1885, page 810). It has long had an extensive local reputation, and is freely used by the practitioners of Chili and other South American countries. It is considered to be of special value in vesical and renal troubles arising from the uric-acid diathesis, and is said to favor the expulsion of gravel and small calculi. It also acts as a sedative on the irritable mucous membrane, modifying the secretion and subduing the pain. Its use has been extended to all forms of acute and chronic inflammation of the urinary organs, and numerous reports of cases in which it has been employed tell of its beneficial action, not only in cystitis and vesical irritation due to simple causes, but also when these have arisen from gonorrhœal and prostatic disease. A special indication for its use is said to be the presence of pus in the urine. Dr. Reginald Harrison, after using the drug for four years in private and hospital practice, stated that he obtained considerable benefit from it, particularly under the following conditions; 1. In renal colic and the passing of calculi through the kidneys and along the ureters attended with hæmaturia; though not exercising any solvent power, it seems by its action on the tissues in some way to favor the escape of the stone, and thus to suppress the bleeding. 2. In the hæmorrhage which frequently accompanies cancer of the bladder. 3. The sedative action of the drug on the mucous membrane of the bladder has proved beneficial in many instances of irritability connected with an enlarged prostate.

In addition to its employment in urinary disorders, it is recommended for the relief of the headache, dyspepsia, and other symptoms arising from a condition of lithiasis, and has been used as an hepatic stimulant for jaundice and dropsy due to hepatic disease.

The drug is generally administered in the form of a decoction or fluid extract. The decoction is prepared by adding one ounce to twenty ounces of water, the whole to be given in four portions during the day. The dose of the fluid extract varies between ten minims and two drachms. The average dose is half to one drachm. The effects of the drug are usually experienced after a few doses have been given. The extract is not miscible with water, and the appearance of the mixture is made more pleasant by rendering it alkaline. Glycerine is recommended as the best vehicle for its administration; it is a fairly good solvent, and maintains the drug in suspension in fine particles. Salines should not be combined with it, as they cause the separation of the resin in dense curds. Fluid extracts of hyoscyamus, hydrangea, buchu, and other remedies may be combined when they are indicated. A solid extract has recently been prepared which allows of its administration in powder in capsules. The dose is from two to ten grains.

Beaumont Small.

PICRIC ACID. Has been utilized as a therapeutic agent in the treatment of inflammatory skin diseases and in malarial fevers.

The local application of a one to two per cent. aqueous solution has proved of decided value in erysipelas. It is to be applied from five to ten times a day and the solution allowed to dry upon the part. Its power of reducing the inflammation is supposed to be due to the fact that it penetrates the corneous cells of the skin, and by its astringent property acts as a proteetive to the Malpighian layer of cells; it also acts as a parisiticide upon the specific cause of the disease. It has also proved of service in eczema and erythema.

As an antiperiodic it is employed in the form of the *picrate of ammonium*. This salt is formed by saturating a solution of picric acid with carbonate of ammonium, or with ammonia. After carefully concentrating the solution, it is allowed to crystallize. It forms in yellow needles, very bitter, soluble in water and slightly soluble in alcohol. Like all alkaline salts of picric acid, it requires to be handled with care. When administered for any length of time, it possesses the disadvantage of causing a yellow discoloration of the skin and conjunctiva, and has been known to produce urticaria. As an antipyretic and antiperiodic it is regarded as inferior to quinine, but has the advantage of not causing any gastric disturbances, but rather of suppressing them when they exist. It does not produce the headache, giddiness, and other distressing symptoms that are often caused by quinine. It is indicated in patients suffering from the apyretic form of malaria who are free from cachexia. A Dr. Clarke states that he has treated malarial diseases in India entirely with this drug, to the exclusion of the alkaloids of cinchona. In intermittent fever and in malarial neuralgias and headaches the same success was observed. He gives it in doses of one-eighth to one and one-half grains, four or five times a day, in pill form, the average dose being a half grain. It is best given on the day of remission.

Beaumont Small.

PICROTOXIN. This neutral principle has attracted attention recently, on account of its reputed value as an antidote to opium poisoning, and as a respiratory and

cardiac stimulant in conditions of collapse and chloroform narcosis. The drug stimulates the origins of the inhibitory fibres of the vagus, the vascular and respiratory centres, and the motor areas of the medulla oblongata. By its use the respirations are rendered stronger and more deep, the heart contracts more forcibly, and the blood-pressure is increased by its action through the vaso-motor system. This action, Arpad Bókai (*Centralbl. f. klin. Med.*, Aug., 1889) pointed out, was opposed to that of opium, and rendered it a physiological antidote to poisoning by opium and other narcotics which produced death by paralysis of the respiratory and vascular centres. A number of experiments were performed, which proved its antidotal action. Later experiments of the same observer have to a certain extent modified his views. He finds that picrotoxin undoubtedly stimulates the respiratory centres and increases the blood-pressure and counteracts the toxic effects of small doses of opium; but when very large quantities have been taken it has less power to counteract the lethal action, as full doses of the antidote are liable to induce spasm of the respiratory muscles and hasten a fatal termination. He, however, found that the concomitant ingestion of paraldehyde would prevent this spasmodic action and allow the drug to exercise its effects as an antidote.

The dose that is recommended is one-tenth grain, to be repeated up to one-third grain during the day. The paraldehyde should be given in doses averaging forty-five or ninety minims daily.

Further experiments upon animals have demonstrated the efficacy of the drug to counteract the depression that accompanies the profound narcosis of chloroform, urethane, paraldehyde, and amyl hydrate, and suggests its value in all forms of collapse. *Beaumont Small.*

PIERREFONDS. A watering place in the Department of Oise, France.

Location.—Pierrefonds, a place having eighteen hundred inhabitants, is situated near the famous forest of Compiègne. It is pleasantly located in proximity to a small lake, backed by wooded mountain slopes. The springs supply cold sulphate of lime and chalybeate waters.

According to Dr. Vintras ("Mineral Waters of France"): "The sulphurous springs are collected in a reservoir constructed in the lake itself. This reservoir supplies the Thermal Establishment, which comprises twenty-one bath-rooms, eight douche-rooms, one ascending douche, and a large room for inhaling the sulphurous water in a state of pulverization. The *buvette* is placed in a little pavilion at the extremity of the park belonging to the company, and is supplied by a special spring. These waters are perfectly clear when they issue from the springs, but grow turbid on contact with the air, and become first bluish and semi-opaque, then white and milky, and ultimately deposit sulphur on the walls of the basins. Their smell is like that of addled eggs, and their flavor, though slightly resembling gall, leaves behind no disagreeable after-taste."

Analysis.—One thousand grammes of the sulphuretted water contains:

	Grammes.
Sulphuretted hydrogen, free	0.0022
Sulphide of calcium	0.0156
Sulphate of lime, Sulphate of soda	0.0260
Bicarbonate of lime, Bicarbonate of magnesia	0.2100
Chlorides of sodium and magnesium	0.0220
Silica and alumina, Salts of potash, Organic matter	0.0500
Carbonic acid and nitrogen	traces
Total	0.3258

Indications.—The Pierrefonds waters are employed for drinking and "pulverization." Vintras states that the treatment with pulverized water originated at Pierrefonds, and the credit of its conception is due to the distinguished Inspector, Dr. Sales-Girons. It is carried on in a special room, admirably arranged and fitted up for the purpose, during periods ordinarily of forty-five minutes each. Baths and douches are also used at Pierrefonds, but not on so large a scale.

The treatment at Pierrefonds is chiefly applicable to pharyngitis, laryngitis, and other diseases of the upper air-passages. Asthma, bronchitis, and even phthisis are said to be favorably influenced by a "course" of the water.

In regard to the chalybeate spring, the writer already quoted says that it is situated at a few paces from the sulphurous *buvette*, and covered by a little pavilion. The iron which it contains is in the form of bicarbonate and arseniate of iron, as has been shown by chemical analysis.

After affections of the respiratory organs, those which are most frequently met with at Pierrefonds are chlorosis, anæmia, amenorrhœa, and dysmenorrhœa (which are beneficially affected by the combined use of the two different waters), rheumatism, and certain diseases of the skin.

Accommodation.—While not a fashionable spa, Pierrefonds offers mild amusements to the visitor. The lodging-houses are neat and clean, but unpretentious. There are pleasant excursions in the immediate neighborhood, and shaded walks abound. The season lasts from June to September. Prices are moderate. The natives are exceedingly obliging. *Edmund C. Wendt.*

PIPERAZINE (Diethylene—Diamine. Ethlenimine). A synthetical compound primarily intended to replace spermine, but found to be a different body, both in chemical and in physiological characters. It is now utilized only as a solvent for uric-acid deposits in the place of lithia salts.

It is formed from the action of ammonia on ethylene bromide, which produces a mixture of compounds from which diethylene diamine is separated by fractional distillation at a temperature between 130° and 180° C. When separated by a patented process it is supplied to the profession under the name of piperazine. It is a solid which melts at 104° to 107° C., and boils at 145°. It forms in bright, lustrous tables. When exposed to the air it absorbs water and carbonic-acid gas, and becomes liquefied. It is very soluble in water, and forms a tasteless, alkaline solution without being in the least corrosive. An hydrochlorate is prepared which is also very soluble in water, and forms in silky, lustrous, lanceolate crystals. The following test is given for its detection in urine:

About 10 c.ctm. of urine are decomposed with a few drops of concentrated soda, and slightly warmed for a short time. After cooling, the liquid is filtered from the flocculent precipitate (phosphates, etc.), made decidedly, but not too acid, by a few drops of hydrochloric acid, and decomposed by potassium bismuth-iodide. First, a dirty-colored amorphous precipitate is formed, which contains no piperazine, but is produced by the nucleo-albumin which is a constituent of normal urine. The mixture is then warmed for a short time to about 40° to 50° C. (whereby the precipitate aggregates), rapidly cooled, and filtered. On energetically rubbing with a glass rod, the bismuth compound gradually crystallizes out and falls as a fine red powder.

The compound separated from such a dilute solution can be readily and certainly identified. It consists of characteristic and constant stellate groups of crystals of bismuth—piperazine.

Experiments with solution of piperazine upon uric acid and upon calculi formed of uric acid and uric acid with phosphate of lime, prove that it exerts a powerful solvent action. When placed in a one per cent. solution at a temperature of 90° F., the stones are rapidly acted upon, the sharp edges are removed, and the surface becomes smooth and slippery; within twenty-four hours the mineral portion is dissolved and a soft mucoid skeleton only remains. All forms of urinary deposits are said to be, more or less, acted upon. Compared with carbonate of lithium it dissolves twelve times as much uric acid. Tests have been made of the relative solubility of fragments of a stone in one per cent. solutions of piper-

azine, lithia carbonate, borax, and sodium carbonate. In the piperazine solution the fragment was dissolved in six hours, the lithia solution did not dissolve until after forty-eight hours, the borax dissolved only a very small portion in forty-eight hours, and the sodium solution had no effect whatever after the same period. In each case the residue was placed in the piperazine solution, when it entirely disappeared. A very important characteristic of the piperazine urate that is formed is its great solubility; even when an excess of uric acid is acted upon only the soluble salt is produced. This is seven times more soluble than the lithia salt. One part of the latter requires three hundred and sixty-eight parts of water for its solution, while one part of the piperazine urate is soluble in fifty parts of water.

The physiological action when administered in health is perfectly harmless. It does not disturb in the slightest degree the functions of the digestive, circulating, or respiratory organs. Even when introduced directly into the blood its effects are negative. After its administration and absorption it is not decomposed or acted upon in any way, but passes through the system and is excreted by the kidneys unchanged. Piperazine may be detected in the urine two hours after its administration, and it continues to be excreted for a prolonged period. The urine is not rendered alkaline, nor in any way altered by its prolonged use.

It is evident from these properties that piperazine is theoretically a very valuable drug for the treatment of all conditions in which uric acid is formed in excess. It has been very extensively used in Germany, and numerous cases are reported in which it was used with very marked success — in gout, in all its forms, in lithiasis, renal calculi, vesical calculi, and in many forms of rheumatism of a gouty character. In these conditions it is supposed to first saturate the uric acid that remains dissolved in the organism, and then to attack all deposits of uric acid. The soluble urate of piperazine that is formed is readily excreted with the urine. The piperazine that is not neutralized in the system comes in contact with calculi and deposits in the kidney and bladder and there exerts its specific properties. In gout it relieves the painful joints, improves the digestion, and counteracts all the ill effects of the uric-acid diathesis. The deposits about the joint are diminished and any further increase in size prevented; where these deposits have ulcerated through to the surface the local application of a solution of piperazine hastens resolution and healing of the part. In lithiasis it is reported to act instantly and to give permanent relief, the surfaces and sharp edges of the gravel are rendered smooth and the expulsion favored. In many cases the small calculi are passed within twenty-four hours, and the urine becomes clear and free from deposit in a few days. On account of its freedom from any irritating action on the mucous membrane, it may be made to act directly upon the deposits in the bladder, by injecting a one per cent. solution, which assists in the decomposition of the larger calculi that would otherwise require operative treatment.

The results of its use have not always been so favorable. Professor H. A. Hare reports having employed it in some cases of well-marked gout and in gouty rheumatism without any beneficial effects. He administered it internally and by hypodermic injection in the usual doses without relief. Sir William Roberts, in the "Croonian Lectures for 1892," on the treatment of the uric-acid diathesis, states that piperazine in blood-serum or synovia had not the slightest effect in adding to the solvent powers of these media on sodium biurate, nor the slightest effect in retarding its precipitation from serum and synovia artificially impregnated with uric acid. He concludes that if piperazine has any beneficial action in gout it is not due to its solvent powers on the material of gouty concretions. The drug, however, appears to be worthy of an extended trial. The numerous reports of its successful employment and its freedom from any ill effects are in its favor, and there is little doubt but that it will be extensively used and its position as a remedial agent more definitely established.

On account of its hygroscopic properties it must never be prescribed in powder or pill form. It is supplied in bottles containing five grammes, which is sufficient for five days' use. This is to be dissolved in a definite quantity of water, and one-fifth given each day in divided doses. The quantity employed by all observers has been one gramme daily, in solution, well diluted. The effects of the drug are rapidly manifested, but its use may be continued for a long time without producing any unfavorable symptoms. After the subsidence of the attacks a smaller dose of eight to fifteen grains may be given every third day, and continued for months. When administered hypodermically, fifteen minims of a ten per cent. solution may be used. The injections are to be made in the neighborhood of the affected joints. The drug is to be given internally at the same time. The effects of this method are reported to be very gratifying; the swelling and pain subside and the deposits are absorbed and greatly reduced in size. In some cases it is reported that deposits of gouty material in the pinnæ of the ears and in the eyelids were removed by two or three injections. The following solution is also prepared for its local application to the affected joints: Piperazine, 15 to 30 grains; alcohol, 5 drachms; water, 2½ ounces.

Dr. David D. Stewart (*The Therapeutic Gazette*, January, 1893) contributes a very valuable report of cases treated with satisfactory results.

Piperazine has recently been employed as a remedy for the treatment of epilepsy; the preliminary observations are reported to be favorable, but the results of its use in this disease are not yet known.

Beaumont Small.

PLOMBIÈRES. This spa has already received a brief notice in Vol. V. of the HANDBOOK. The place is sufficiently important, however, to deserve some additional attention. Plombières has been called, not without reason, "the Queen of Watering-places of the Vosges." It is charmingly situated, and its surroundings are so attractive that it is a favorite summer resort with many who have not been ordered there for a course of the waters. The little town has only about 2,000 inhabitants. It is situated in a narrow valley, with mountains rising steeply up on either side. The climate is invigorating, and, while the days in summer are often hot, the nights are invariably cool.

A special feature at Plombières is the long time (one-half to one and a half hours) during which patients remain in the water. Mr. Wolff ("The Watering-Places of the Vosges") says that only four springs out of the twenty-seven which are now in use at Plombières, are drunk at all. The first is the chalybeate, which is very mild, and is employed mainly as a table-water and as an adjunct to bathing in cases of anæmia and chlorosis. Another spring used for drinking, and also for bathing, the "Source Savonneuse," is mildly laxative. Besides these, the "Source des Dames" and the "Source du Crucifix" are employed for what little drinking there is. Apart from the chalybeate and the Savonneuse, the Plombières waters all belong to one category. Dr. Constantin James calls them alkaline; Dr. Bottentuit, "*arséniatées sodiques, sulfatées et silicatées sodiques;*" M. Jacquot, "*bicarbonatées sodiques silicatées;*" and Dr. Macpherson, "indifferent." The latter designation is most in keeping with their slight degree of mineralization.

The same author states that, "in addition to the baths, a very effective remedy in some cases applied at Plombières are the *étuves*, also called *étuves de l'Enfer*. These are hot vapor baths, for which the heat and vapor are supplied by the running springs. There are two such establishments, both of course underground, and both, at their hottest points, very hot indeed. But for people who cannot stand excessive heat, there is the convenient institution of *étuves en boîte*, which are taken in a closed box, with a hole left in the top for the head." Energetic massage is also much employed at this spa; so that the patient's time, what with drinking, bathing, walking, douching, massaging, and dieting, is quite fully occupied. Most of the visitors are women, al-

though it is by no means an exclusively "female watering-place."

The place is rich in mineral springs, but the proportion of solids in the waters is rather insignificant. Over twenty-five springs are used at Plombières, and the water of most of them is collected into a single conduit and conveyed to the different thermal establishments. Only three of the latter are perfectly modern and satisfactory, viz., the *Nouveaux Thermes*, the *Bain Romain*, and the *Bain Stanislas*. Although so slightly mineralized, the varying temperature of the baths (65° to 160° F.) admits of a certain amount of variety in treatment. The waters are easily borne when taken internally, and do not produce any constitutional disturbance.

ANALYSIS—One thousand parts of the water contain in parts:

A course of Plombières is useful in many nervous states, especially those associated with hyperæsthesia, as well as in those depending upon lithæmia. Many symptomatic neuralgias and paretic conditions derive benefit from a course of treatment at Plombières. Stiff joints may be limbered up, lumbago cured, gouty manifestations alleviated, diseases of women improved. The place also has quite a reputation for the cure of sterility, though on what grounds does not specifically appear. The waters are also applicable to cases of gastralgia, dyspepsia, catarrhal conditions of the bowels, especially when accompanied by chronic diarrhœa. Some skin diseases, such as eczema and psoriasis, are likewise said to be greatly benefited by these waters. The chalybeate springs are, of course, useful in anæmia and chlorosis. In phthisis the place is said to be contraindicated.

Plombières is a decidedly international watering-place, although English and Americans form but a small contingent of the six thousand annual visitors of the spa. With reference to accommodation, Mr. Wolff is authority for the following: "The better hotels and villa-pensions seem intended for people altogether of the better classes. They are good, but dear. Of course, there are less pretentious ones, down to the lowest point of the scale. For the spa is much visited. The following are among the best: The Grands Hôtels, Hôtel de la Paix, Hôtel Stanislas, Villa Mocquard, Le Chalet Rose, and Maison Rossignol. There are as many as about a hundred private hotels, many of them with a regular table d'hôte." Altogether, it is quite true that Plombières should be better known in our country than is now the case, especially as it is more convenient of access than Wildbad, Gastein, Teplitz, and the other spas of that order, which Americans are wont to visit. *Edmund C. Wendt.*

POTT'S DISEASE. HISTORY.—This disease was not first accurately described by Percival Pott, as has been stated. A year before Pott wrote his classic paper ("Remarks on that Kind of Palsy Affecting the Lower Limbs," etc., London, J. Johnson, No. 72 St. Paul's Churchyard, 1779), Jean Pierre David gave a full account of the disease in a Prize Essay, *Dissertation sur les effets du mouvement et du repos dans les maladies chirurgicales*, the subject proposed by the Royal Academy of Surgery at Paris for the year 1778. This essay was translated and appeared among the "Surgical Tracts," by the late J. C. Justamond, collected and interspersed with occasional notes and observations by William Houlston, and printed in London for T. Cadell, in the Strand, in 1779. Here is M. David's description of a case which he saw at the hospital in 1776: "Having been violently beaten, at the age of thirteen, by his father, he felt, a few months after, a weakness in the spine, attended with pain and a difficulty in keeping the upright posture. He at first walked with great difficulty, and afterward could not walk without leaning upon a stick, with his body bent forward. These symptoms, which continued more than six months, were followed by a fever, accompanied with difficulty of breathing, and pain in the middle of the back without any very apparent swelling externally. These symptoms were relieved by bleeding and other remedies, and the patient seemed restored to his former state, but the difficulty of walking and of supporting himself increased by degrees, and at length a tumor was formed toward the lateral and posterior part of the last false ribs, the increase of which was very slow, and made no change in the color of the skin. This tumor, extending itself, gained the region of the loins, and more than six months after its appearance the skin became inflamed, grew thin, and by the assistance of maturating poultices applied to the tumor, a fistulous opening was made in it, from whence there issued, according to the patient's account, more than a quart of matter as white as milk. This discharge having continued very plentiful for three months without hopes of cure, the parents, tired with the length of the disease, took the resolution of sending the young lad to the hospital. When he came there he had a fistulous opening on the right side of the lumbar region, which furnished an ichorous and plentiful discharge; a slow, suppuratory fever accompanied, and every appearance seemed to show that death would soon terminate this disorder. A pledget of soft ointment only was placed upon the fistulous orifice, and the disease was left to nature. I frequently saw this patient, who, being better fed, and more attended to than at home, began to recover a little from the deplorable state to which he had been reduced. He particularly kept very quiet in his bed; and his spine was then incurvated with an evident projection outward, toward the last dorsal vertebra. Almost two months after he came into the hospital, the matter which oosed from the fistuluous opening grew thicker and less plentiful, the countenance appeared better, the pulse less frequent, and he began to give some hope of recovery. This hope was more confirmed six months after, for the patient began to feel some degree of strength in the spine. Two months after this last period the fistulous orifice was closed, and the patient began to walk with a stick; but he was crooked, and seemed to have lost much of his former height. From the accidents this patient had undergone, and the deformity the spine had contracted during the course of the disease, I imagined that some of the dorsal vertebræ had been affected with caries; that the remains of them, after being confounded together, and after having been in a state of granulation, had at length acquired a degree of solidity sufficient in some sort to supply the place of the bodies of these bones. I could not but consider rest as having been the chief promoter of this salutary end; the subsequent facts appear to have completely confirmed my conjectures on this point. First, the patient, who had been the subject of the preceding observation, and whom I had always kept within my notice, having been seized in 1769 with a peripneumony, of which he died, I was allowed to inspect the body, and my first care was to take notice of the disorders the spine had experienced three years before.

I found, as I suspected, several vertebræ, the bodies of which were confounded with each other; these were the ninth, tenth, and eleventh of the dorsal vertebræ, which had lost at least half of their longitudinal dimensions, while the spinal processes, which had not suffered the least alteration, formed the projection and a remarkable convexity outward."

There has, perhaps, never been drawn a more perfect picture of a case of Pott's disease; if there has, it was not drawn by Percival Pott.

David differentiated these cases from lateral curvature; he noted the manner in which the abscesses differed from other abscesses as to their contents, the course without treatment and after incision, and as affected by rest of the diseased spine, and his ideas of their proper treatment were the same as those held by orthopedic surgeons of the present day; and the principles of the treatment which he advocated were the same as now govern the management of this disease.

Pott's paper, published a year after David's, treated of the paraplegia accompanying some of these cases. He says: "The disease of which I mean to speak, is generally called a palsy, as it consists in a total or partial abolition of the power of using, and sometimes of even moving, the lower limbs, in consequence, as is generally supposed, of a curvature of some part of the spine." He condemned the use of "steel stays, the swing, the screw chair, and other pieces of machinery." In treatment, Pott, following Dr. Cameron and Mr. Jeffrys, of Worcester, "made an issue by an incision on one side of the projection, and gave strict charge to the mother to take care that the pea was kept in." At times he used a seton on each side of the projection, and at other times he made eschars with caustic, then inserted kidney beans, and sprinkled the bottoms of the sores every third or fourth day with powdered cantharides. Nowhere in Pott's paper is there evidence that he opened the spinal canal post mortem, or suspected the true pathology of the cause of the paralysis. His observations were solely confined to a consideration of the clinical phenomena during life, and of the superficial bony alteration after death. Pott's paper was written for the purpose of advocating a novel treatment by inducing superficial suppuration, and David's for the purpose of illustrating the value of rest in the treatment of these and other chronic bone and joint diseases; neither appears to have thought that in the description of the outward manifestations of the disease there was anything new to advance.

Paraplegia.—When the tubercular growths in the body of a vertebra have caused a perforation at the posterior surface, and a destruction of the periosteum of this surface, the tuberculous inflammation begins to spread in the epidural space. In this way partly tubercular granulations, partly tubercular abscesses, press the dura mater upon the cord. Reaction takes place in the dura, but a specific inflammation of this membrane does not yet occur; the process still remains a peri-pachymeningitis. It is only after the process has lasted for some time that the peri-pachymeningitis becomes a pachymeningitis; but even then the process is limited for a long time to the outer layers of the dura mater. If the patient lives long enough, the process finally passes through the dura, and then assumes the characteristics of a typical tuberculous inflammation of the cord. Thus this specific tuberculous myelitis never sets in until near the end of the disease, to which the patient succumbs.

Very soon after the invasion of the epidural space by the tubercular process, the cord begins to show functional disturbance. This may sooner or later pass on to complete paralysis. This has been shown to be due to the pressure of the new growth. The pressure interferes with the flow of lymph from the cord, and a stasis results. After the œdema has existed for some time the lymphatic fluid acts as a poison to the nerve elements of the cord. It first increases, and then decreases, and often open spaces are left in the neuroglia; a softening of the cord occurs, but at the same time an hypertrophy of the interstitial connective tissue, so that finally complete sclerosis results.

Paraplegia is by far the most frequently associated with disease of the first three or four dorsal vertebræ, occasionally with disease in the lower cervical bones, and rarely with disease in the lower dorsal and lumbar regions. It may come on before deformity or any other symptom has been noticed, or at any time during the course of the disease. It has no definite relation to the acuteness of the angle or the shortness of the radii of the curve, and it may be recovered from, while the deformity grows worse. The duration may be for a few weeks, or it may last for months or years; relapses occur in a certain number of cases. Loss of sensation, and of control of the bladder and rectum, is comparatively rare. Treatment is of no avail except as it is directed to the cure of the bone lesion, namely, immobilization and recumbency. Much has been claimed for iodide of potash administered in heroic doses, but it has not been demonstrated to be of the slightest benefit except in the children of syphilitics, and counter-irritation by blisters, issues, and the actual cautery are as useless as they are brutal. Treated by uninterrupted immobilization and recumbency nearly every case ultimately recovers.

Abscess.—The abscess of Pott's disease is not a true abscess in the sense of containing pus and the microbes of suppuration. The lining membrane of the cavity is made up of miliary tubercles embedded in fibrin, and the contents are the liquefied product from the degeneration of this new growth. In the fluid "pus" no germ elements are found except the tubercle bacillus, and only in a limited number can even this be demonstrated by microscopic examination or culture experiment. Nevertheless, inoculation in fit subjects always results in tuberculosis, and proves the nature of the process.

Fig. 522.—Lateral Deviation, with Rotation, in Pott's Disease; old case.

The treatment of these tubercular abscesses is less satisfactory than that of similar abscesses connected with tubercular osteitis elsewhere. They usually form first on the anterior surface of the spinal column, and before they

are demonstrable or accessible have formed numerous pockets and tortuous tracts. Complete evacuation by aspiration or incision is rarely possible, and unless accomplished renders the operation useless, and adds the risk of infecting the cavity with septic elements. This fact, and the knowledge that a very considerable number of these abscesses disappear without evacuation, if only the bone disease be effectually treated, has led the majority of orthopedic surgeons to a let-alone policy, which eventuates in reabsorption or spontaneous opening and evacuation. Simple aspiration is no longer practised. If an aspiration is attempted, it is conducted with full antiseptic precautions, and followed by the injection into the cavity of a mixture of sterilized iodoform in glycerine and water or olive-oil. If an incision be made, the contents of the cavity should be carefully and as thoroughly

Fig. 523.—Marked Lateral Curvature, with Rotation, in Pott's Disease; recent case; rear view.

as possible washed out with sterilized water, the iodoform mixture injected, and the cavity closed without drainage and with carefully adjusted compression. In a certain number of cases a more rapid cure is effected by such treatment.

Lateral deviation of the spine, either with or without rotation, is a frequent early symptom of Pott's disease. The rotation, affirmed by Bartow and denied by Lovett, unquestionably exists in some early cases, and is quite universally present in those cases where the lateral deviation has existed for some time. (Figs. 522, 523, 524.) Fig. 525 shows the profile as the patient bends forward, the parallel lines *a* and *b* (in the latter figure) drawn from the spinous processes indicating the extent of the lateral deviation.

Early Symptoms.—In cervical disease, before any deformity has taken place, and often while the restriction to passive motion is still uncertain, if the patient be placed first prone and then supine across the parent's knees, the head will not be allowed to dangle, no matter how long the position be maintained. In dorsal and lumbar disease, forward bending, when the patient sits on the table or floor with knees straight, will be more restricted than passive backward bending with the patient lying prone.

Differential Diagnosis.—We need only refer to scoliotic and rachitic curves. In scoliosis the curve does

Fig. 524.—Front View of Same Patient.

not become rigid until it has existed for some time, and the deformity has become quite severe, while in Pott's disease early rigidity is the diagnostic symptom. Rachitic curves only occur in infants, and rarely without other rachitic manifestations. The curve is never angular, but it may be fairly rigid.

Prognosis.—Dr. Samuel Ketch, from a study of seventy-five cases, found that the average time of treatment

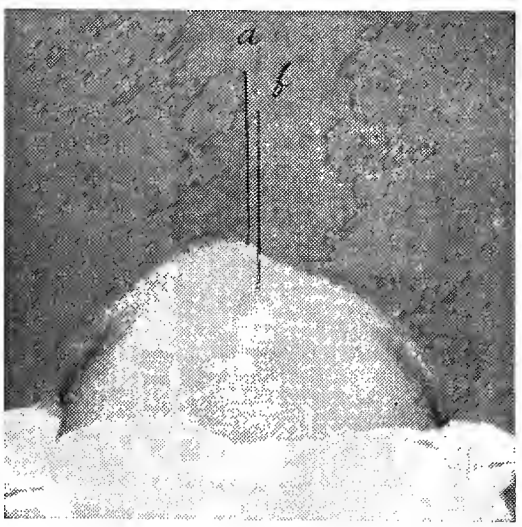

Fig. 525.—Same Patient as in Fig. 522, Bending Forward, showing Amount of Rotation.

in obtaining a cure was $26\frac{1}{28}$ months in the superior region, $64\frac{8}{28}$ months in the middle region, and $47\frac{11}{28}$ months in the inferior region.

TREATMENT.—The treatment of Pott's disease aims to immobilize, more or less perfectly, the area of disease, and to wholly remove the superincumbent weight by recumbency, or to partially remove it by some apparatus. When the plaster-jacket was first used it was believed to support, by its circumferential grasp, the chest, and by the jury-mast the head, by transferring their weight to the pelvis.

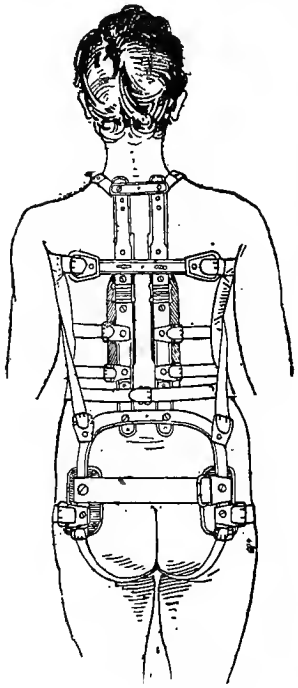

FIG. 526.—The Taylor Spinal Brace.

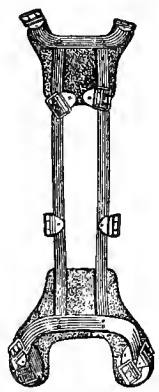

FIG. 527. — Modified Taylor Spinal Brace.

This it does not do, but it does by its leverage action take some of the superincumbent weight off the diseased vertebral bodies. In the same way do all braces act that prevent increase of deformity. In no way can the whole of the superincumbent weight be removed except by recumbency, and even then destructive pressure between the diseased surfaces from muscular spasm is not always avoided.

Immobilization of the diseased bones is conducted upon three different principles, namely: To correct the deformity in so far as is possible by partial suspension, practised at considerable intervals, and immobilization by plaster jacket during these intervals; secondly, to correct the deformity, in so far as is possible, by continuous antero-posterior leverage by means of a brace, which uses the transverse process of the vertebræ of the kyphosis as a fulcrum; thirdly, to immobilize, by the longest possible lever which uses the whole width of the back as a fulcrum, without any attempt at correction of the deformity. A fourth plan is that used by Blanchard, of Chicago, who attempts a rapid correction of the deformity by longitudinal traction and lateral pressure from weights, while the patient is in prone recumbency, followed by the application of a "shell-back" brace, moulded over a plaster-cast of the back to a comparatively accurate fit.

The plaster-jacket has already, in the earlier part of this work, received full consideration, and the wood and paper corsets, acting upon the same principle, will be fully described under Scoliosis.

The principle of the Taylor antero-posterior spinal brace has already been set forth in the earlier part of this work. The brace shown in Fig. 526 is the latest form of the brace as used by Dr. Taylor. Properly fitted, it is, in the writer's opinion, the most effective of the spinal braces. It is, however, an expensive brace, and not readily measured for and obtained in such shape as to be readily fitted and satisfactorily worn. An inexpensive modification is shown in Fig. 527. In cases where the deformity is not too great it will be found a most satisfactory apparatus.

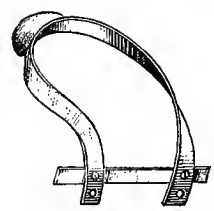

FIG. 530. — Chin-piece to Whitman's Brace.

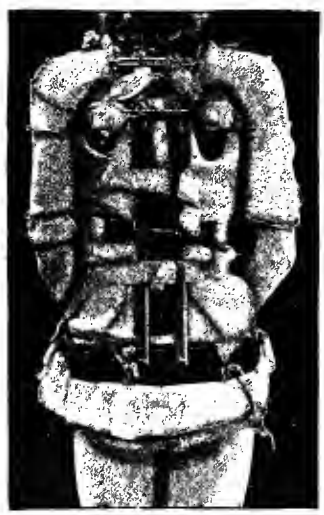

FIG. 531.—Whitman's Brace.

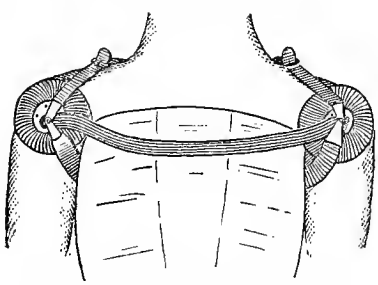

FIG. 528.—Whitman's Brace; front view.

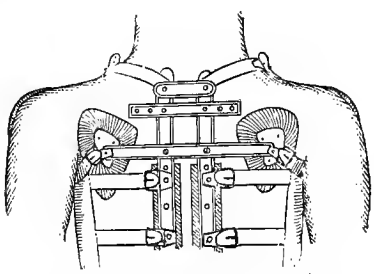

FIG. 529.—Whitman's Brace: rear view.

An effective brace for disease in the mid-dorsal region is that of Whitman, shown in Figs. 528, 529, 530, 531, 532 and 533. It prevents forward drooping of the head and perfectly supports the shoulders.

Of the braces that immobilize by a long leverage action upon the entire back without any attempt to correct the deformity, the Thomas cuirass forms the best example. This is shown in Fig. 534. It consists of an irregular oblong frame of flat bar-iron, shaped to fit the contour of the spine, and reaching from the base of the neck to the level of the greater trochanters. This is padded on the side next the patient with felt, and the whole covered with leather.

Fig. 532.—Whitman's Brace ; side view.

Fig. 533.—Whitman's Brace, with Chin-piece Applied.

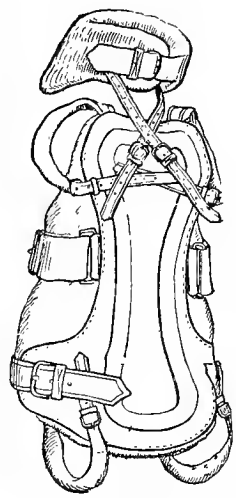

Fig. 534.—The Thomas Spinal Cuirass, with Collar.

A brace somewhat similar in its design and action is that of Wallace Blanchard, shown in Fig. 535. This is

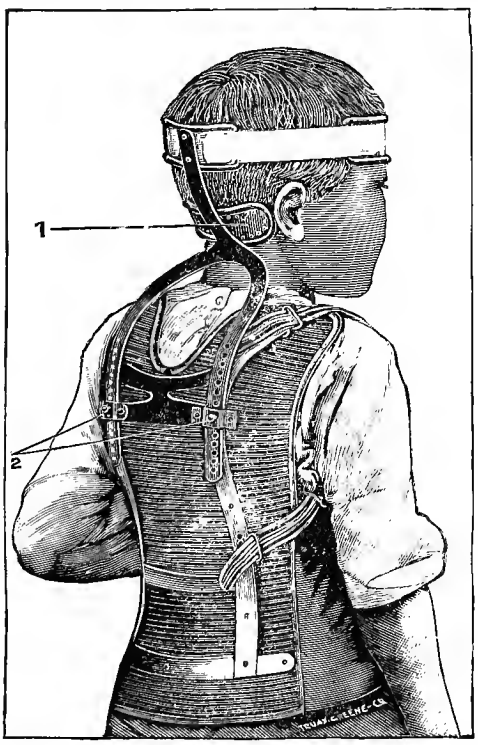

Fig. 535.—Blanchard's Brace.

made to fit accurately over a plaster-cast of the spine, taken when the deformity has been corected in so far

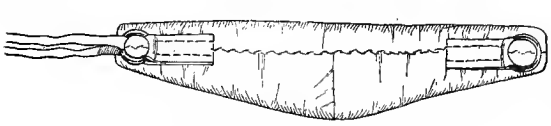

Fig. 536.—The Thomas Collar.

as is possible by longitudinal traction and lateral pressure.

For cervical caries a simple and effective device is the Thomas collar, shown in Figs. 536, 537, 538. It is made

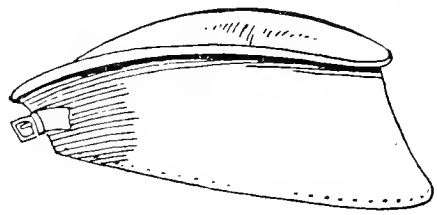

Fig. 537.—The Thomas Collar.

from thin sheet-iron, zinc, or tin, wrapped in felt, and the whole covered with basil leather. It fits the neck snugly,

Fig. 538.—The Thomas Collar Applied,

but not to strangulation, and so completely fills the space between chin and sternum that no motion is permitted.

John Ridlon.

POTT'S PARALYSIS IN CHILDREN. FREQUENCY.—The ratio of cases of spinal caries in which paralysis is a complication to the whole number of cases, varies greatly with the clinic of the one making the estimate.

	Cases of spinal caries.	Paralyzed.	Per cent.
Gibney [1]	295	62	21 0
Taylor and Lovett [2]	445	59	13.0
Mohr [3]	72	5	7 0
Drachman [4]	166	22	13.6
Sayre [5]	109	38	35 0
Total	1,087	186	17.0

SYMPTOMATOLOGY. *Prodromal period.*—There may or may not be a prodromal period characterized by sensory disturbance. This may be pain, varying much in degree; it may be girdle-like, or there may be persistent neuralgias at any spot of the abdomen or legs. Possible also are paræsthesiæ, as tinglings or sensations of heat or cold, hyperæsthesia and anæsthesia; anæsthesia occurs usually in spots.

PARALYSIS OF MOTION.—The paralysis which is characteristic of the affection varies from a slight weakness of a few muscles, not to be noted without close observation, to a complete loss of power of most of the muscles of the body, so that the patient lies prostrate. Though usually a paraplegia, the paralysis may be a monoplegia or a hemiplegia, or it may involve all parts of the body supplied by spinal nerves; any form, too, may develop after a time into a paraplegia. There may be a brachial paraplegia, and later this may extend and involve the legs. In severe cases the abdominal and respiratory muscles may be affected. The legs are very often affected unequally. Of 58 cases reported by Gibney,[1] 24 (40.6 per cent.) had complete paralysis of the affected parts, and of these 4 had also incomplete cervical paraplegia. Of 59 cases analyzed by Taylor and Lovett,[2] 32 (54.2 per cent.) had complete paralysis, and 3 had paralysis of the arms. Of 83 cases in children under sixteen, tabulated by the writer, 27 (32.5 per cent.) had absolutely no power of motion in the legs, and of these, 12 had also to a greater or less extent paresis of the arms.

PARALYSIS OF SENSATION.—"Some impairment of sensation is found in all Pott's paralysis, but it is usually so slight as only to be recognized by the most delicate tests and for a short time" (Bradford [6]).

Very frequently, however, sensation in the paralyzed parts is decidedly dull, usually some time after the muscular weakness is noted, and there may be almost complete anæsthesia of all the body below the site of compression. This is significant, of course, of a very extensive transverse myelitis. Hemianæsthesia, or areas of anæsthesia, are sometimes found, and there may be, though usually there is not, pain of a constant heavy aching character all over the paralyzed limbs. There may be also paræsthesia and hyperæsthesia, all of these sensory symptoms being due to compression or myelitis of the posterior columns. Generally tactile sense disappears first, then the sense of temperature, and last the sense of pain (Erb).[7] Michaud [8] quotes a case in which there was paralysis of sensation and not of motion, and there are several cases in which the sensation was found dull before muscular weakness was noted. Taylor and Lovett [2] found, out of 59 cases, 15 (25.4 per cent.) with incomplete sensory paralysis. Of the writer's 83 cases, some degree of sensory paralysis was noted in 30 (36 per cent.).

SPASMS AND CONTRACTURES.—In the prodromal period there may be twitchings of various muscles, due to irritation of the anterior nerve-roots, but as a rule, at first the paralyzed muscles are completely relaxed, quiet, and soft; the joints are also relaxed and do not oppose passive motion. In the later stages, with the advent of secondary degeneration in the cord, the flaccid muscles may become tense and rigid; usually at first the rigid legs are extended and the feet held in slight equinovarus, but later a change comes on slowly or suddenly, sometimes while the patient is asleep; the thighs become flexed on the pelvis and adducted, the legs flexed on the thighs, and the feet frequently take the position of calcaneo-valgus. If the limbs are extended again they will often flex in a jerk without any apparent cause. In some cases there is present what has been called "clasp-knife" rigidity (for example, if, when the knee is flexed, the leg is gradually straightened, it moves smoothly and easily till full extension is nearly reached, and then it suddenly becomes rigidly extended, and considerable force is required to bend the knee again). At first abnormal positions can be readily passively corrected, but later contractions set in and the legs become fixed in the position adopted. Of the writer's 83 cases, 12 (14.4 per cent.) were observed to have rigid muscles.

BLADDER AND RECTUM.—In severe cases the bladder or the rectum or both may be affected. Usually at first there is difficulty in micturition, shown as slowness in starting the stream, but later there is true incontinence. The anal sphincter also may be paralyzed, but unless there is diarrhœa, the paralysis may not be noted. The involuntary evacuations may be conscious or unconscious. Incontinence may result apparently from downward extension in the cord some months after symptoms of complete paraplegia have existed, and this incontinence may last for years, and yet the patient finally improve and obtain entire control over the bladder again. In other cases, the resulting cystitis is an important factor in causing death. Taylor and Lovett,[2] in 59 cases, find 8 with paralysis of bladder or rectum, and in the writer's 83 cases 34 made some complaint of weakness of sphincters.

REFLEXES.—The condition of the deep reflexes is of diagnostic value. They are regularly exaggerated, unless the seat of the lesion be the lumbar enlargement, in which case they are absent. The slightest tap on the patellar tendon, the lightest pressure on the sole of the foot, even a tap on the bone or fascia, or belly of muscle, will in many cases call forth a vigorous contraction of all the muscles of the leg, and sometimes be followed by a similar contraction of the muscles of the other leg. Even the evacuation of the bladder or rectum is said sometimes to be sufficient to cause a clonus of the limbs. The cutaneous reflexes are sometimes exaggerated, even so much that pinching the skin will cause a violent reflex clonus; again they are not to be found, and still again they are unaltered.

TROPHIC AND VASO-MOTOR CHANGES.—Trophic changes are said to be uncommon, unless the cervical or lumbar enlargement is involved; but if the paralysis has existed any considerable time one frequently finds a notable degree of atrophy of the legs, together with some coldness, occasional lividity, and generally a dry, inelastic, scaly skin. There may be localized œdemas and sweatings, and rarely lesions of the joints secondary to lesions of the cord. Roser [9] has seen three cases of spontaneous dislocation of the hip, brought about by the reflex motions of Pott's paralysis; the luxation was behind, gradual, and painless. In severe cases bedsores are frequent. Of 83 cases noted, 16 (19.5 per cent.) showed some wasting of the paralyzed parts.

MEDULLARY SYMPTOMS.—When the upper cervical cord is compressed, Charcot has noted paralytic myosis and spastic mydriasis, from paralysis or irritation of the corresponding paths in the cervical medulla. Respiratory and gastric disturbances, persistent hiccough, and difficult swallowing or vomiting, as well as retardation of the pulse, have been met, and are attributed to implication of the vagus, spinal accessory, or phrenic.

TIME IN POTT'S DISEASE AT WHICH PARALYSIS APPEARS.—The paralysis may come on as a diagnostic symptom of Pott's disease before the latter has been otherwise made manifest, or it may come on when spinal disease has existed for years, and to all appearances the destructive process has subsided. Taylor and Lovett [2] say paralysis occurs on an average about two years after the beginning of the disease. Gibney [1] sets the average time at three years. The writer has found in 75 children that paralysis came on within a year from the be-

ginning of the disease in 32, in one to two years in 12, in two to three years in 11, in three to four years in 9, in four to ten years in 6, and in over ten years in 5.

Duration of Increase of Paralysis.—From the first note of weakness to the maximum of paralysis attained, there may be less than a day, and there may be several months, but, perhaps oftenest a few weeks. In 44 of the 83 cases studied, this time was noted, with a result as follows: under one month, 19 cases; one to two months, 12; two to three months, 4; over three months, 9.

Duration of Paralysis.—The duration of the attack may be a few weeks or it may be a lifetime; usually it varies from a few months to a few years. Pott [10] put the time at from two months to two years. Gibney [1] in 13 cases found a duration ranging from four weeks to twenty-two months. Taylor and Lovett [2] give as the average duration twelve months, but when paralysis comes on while the patient is under treatment, an average duration of only seven months.

In 66 cases in children in whom the duration is known, the paralysis lasted less than a year in 40, from one to two years in 13, two to three years in 6, and more than three years in 7.

Recurrences.—A few cases have more than one attack, and three and even four attacks have been noted. Taylor and Lovett [2] find in 59 cases recurrences in 6. The intervals between these recurrences vary from a few weeks to some years. Gibney [1] in 58 cases found 8 recurrences, and the writer in 74 children found also 8 with a history of more than one attack.

Terminations.—There are three terminations: recovery, death, and permanent paralysis. 1. Recovery is usually gradual, and frequently lasts months. After a period of absolutely no change in the patient's symptoms, it is found that a few motions can be executed by the paralyzed parts at times; then there is a permanent increase of power in those parts, the sensibility improves, and generally becomes normal before entire power over the muscles is established, control of the bladder is regained and, last of all, usually months after the patient believes himself well, the tendon reflexes become normal.

2. Death may result from progressive myelitis with its attendant cystitis, bedsores, diarrhœa, pyæmic fever, and exhaustion, or the patient may yield to tuberculosis, or be cut off by some intercurrent disease. Gibney [1] in 13 deaths found 6 from myelitis, 2 from tuberculosis, and 5 from other diseases. Taylor and Lovett,[2] in 5 deaths, had 1 from tuberculosis and 4 from intercurrent affections. The writer's cases in children furnish 12 deaths with known causes, distributed as follows: Tubercular meningitis, 2; amyloid, 1; phthisis, 1; exhaustion, 1; after operation, 1; other causes, 6.

3. Permanent paralysis may be slight in amount, simply noticed as a weakness, or it may be a paralysis with contractures, and the patient get about, if at all, with great difficulty. In the last case, however, the general health may be excellent and the condition without danger to life.

Prognosis.—In a broad way the prognosis of Pott's paralysis is good, *i.e.*, it tends to recover entirely. Taylor and Lovett,[2] in 47 cases whose results are known, find 39 recoveries (83 per cent.). Gibney [1] finds in 58 cases 29 recoveries (50 per cent.) In 62 cases in children under sixteen, the writer has found recoveries in 49 (79 per cent.). In making the prognosis in any particular case, certain factors enter which may be considered in detail:

1. *Treatment of the Patient before the Paralysis.*—If the patient has been under treatment the prognosis is somewhat better. Taylor and Lovett [2] give 100 per cent. of recoveries, but the writer has noted 15 such cases with only 10 recoveries (67 per cent.).

2. *Duration of the Paralysis.*—The maximum time with recovery in the writer's cases is four years, and of the 7 cases in which paralysis lasted more than three years, only 3 recovered. In the 24 cases whose paralysis lasted less than six months, 14 (58.4 per cent.) recovered; 16 recovered in from six months to a year, 10 in from one to two years, and 6 in from two to three years. A patient's chance of recovery, therefore, steadily grows during the first year, being considerably greater in the second six months than in the first; it is nearly as good during the second year as during the last half of the first; but the prognosis grows rapidly worse during the third year, and after three years there is comparatively little hope.

3. *Time from Beginning of Spinal Disease to Beginning of Paralysis.*—Of the 32 cases whose paralysis began within a year, 20 (62.5 per cent.) recovered, while of the 43 whose paralysis began more than a year after the spinal disease, 31 (72 per cent.) recovered. In other words, if the process is acute and advancing rapidly enough to bring on a paralysis early, the prognosis is worse than if slower changes compress the cord at a later stage.

4. *Age of Patient.*—Of 22 cases under five years when the paralysis began, 17 (77.3 per cent.) recovered; between five and ten years, 20 of the 36 cases recovered (55.5 per cent.); and between ten and fifteen years about the same percentage of recovery is found. Neglecting other factors, therefore, the prognosis grows better with the youth of the patient.

5. *Severity of the Paralysis.*—In the writer's cases, of those with simple paresis of the affected muscles, 75 per cent. recovered and 15 per cent. died, while in those with complete paralysis of affected parts, 41 per cent. recovered and 30 per cent. died. Fifty per cent. of those with marked sensory, vesical, or rectal affection got well, and twenty per cent. died. Obviously, then, the lighter the paralysis the better the prognosis; but with complete paralysis, the addition of sensory or vesical palsy does not make the chance of recovery materially less.

6. *Location of Lesion.*—Cases other than cervical or dorsal are too few to form a basis for estimate. In 74 children the percentage of recovery in paralysis of cervical origin is 53, while in that of dorsal origin it is 66.

7. *Rigidity or Contractures of Limbs.*—Of 12 cases in which rigidity was prominent, 5 recovered.

8. *Marked Wasting of Limbs.*—Of 16 cases with atrophied limbs, 8 recovered.

9. *Character of Spinal Deformity.*—The kyphosis, as was noted by Pott, is apparently not of great importance in prognosis, but a large gradual curve claims the largest per cent. of recoveries.

10. *Sex.*—As to the liability to paralysis in Pott's disease, it is interesting to note that of the 74 children studied, 34 were males and 40 females. The per cent. of recoveries is about the same in each.

11. *Part of the Body Involved.*—When there is more than a paraplegia present, the prognosis is made correspondingly worse, the per cent. of recovery being in the writer's cases 36, as compared with 62 in children with simple paraplegia.

12. *Recurrences.*—The cases studied give no reason for thinking the prognosis in a second attack any worse than for a first attack.

13. *Intercurrent Diseases.*—The writer has seen two cases of intercurrent typhoid fever; in one, as the fever progressed, the paralysis grew more severe till the patient became powerless, and then lightened with convalescence. The other, a fairly severe case of paralysis, was quite unaffected by the fever. In one case of amyloid disease, which died paretic, there was marked improvement in the paralysis during the two months immediately preceding death.

14. *Proportion of Deaths.*—Taylor and Lovett [2] find 5 deaths in 59 cases, Gibney [1] 13 in 58 cases, and the writer 12 in 86 cases. The mortality of the entire number of cases is 15 per cent.

General Summary of the Prognosis of Paralysis:

1. There is not a symptom characteristic of the paralysis that is of fatal import. Recovery has taken place even from threatening asphyxia.

2. There is hardly a condition of the paralysis so severe as to deny the possibility of recovery. Recovery has occurred from paralysis of arms and legs, anæsthesia, and incontinence.

3. The three most important elements in prognosis in the order of their importance are, (*a*) the duration of the paralysis; (*b*) the completeness of the paralysis of the affected muscles; (*c*) the age of the patient.

TREATMENT.—All authorities agree that the back should be put at rest; therefore confinement in bed or a spinal support, either jacket or brace, must be the first measure adopted. In certain cases this enforced rest, perhaps aided by extension and counter-extension, is sufficient for prompt cure. Relief in a few days or weeks has been given by opening an abscess connected with the spine, and operation is to be recommended if an abscess is present. Subsequent treatment is expectant; the number of drugs given, outside of tonics, is large, and no one is especially useful. After drugs, electricity is recommended, but some orthopedic surgeons are confident that its use has done harm. The cautery [12] and suspension [13] have both been thought to do good in some cases. With reference to all the methods of treatment beyond rest, it is to be noted that as the paralysis tends to a cure, which sometimes comes suddenly and unexpectedly, a careful estimate of the relative value of different remedies is difficult, if not impossible. Some cases, however, do not get well, and even grow worse very rapidly, and for them there has been since 1882 [3] a last resource in resection of the vertebral laminæ at the site of the lesion and relief of pressure. The mortality of the operation is large, but there have been some remarkable successes, and it is distinctly valuable as a last hope. *John H. Huddleston.*

POUGUES. An important thermal station in the Department of Nièvre, France.

LOCATION.—Pongues, or as it is often called, Pougues-les-Eaux, is a small place of about fifteen hundred inhabitants, prettily situated in the valley of the Loire, eight miles from the city of Nevers. Bradshaw ("Mineral Waters, Climatic Health-Resorts," etc.) says that "the situation of Pougues, in a large and airy valley, on the right bank of the Loire, is beautiful, and the impression is never forgotten. The excursions and minor walks are very numerous. The garden and beautiful old park, beginning immediately behind the bathing establishment, are very tastefully laid out, and offer walks of every description. The small lake affords boating. This picturesque part of France has no end of excursions of historical interest, among which we mention Garchizy and its Byzantine church of the twelfth century; Ussy, with the Castle of Bordes; the iron and steel works of Germigny; Castle Villemenant and the valley of Nifont; Poiseux and the fountain of the fairies; Saint Aubin and the wild gorge of the Douée; Premery; the forest of the Bertrange; Champroux; la Charité and the forges of Fourchambault, etc.; all being surrounded by hills covered with magnificent forests. The town of Nevers, with its historical associations and monuments, is equally interesting." The climate is agreeably equable. The season lasts from May to October.

The waters of Pougues are effervescent, cold, calcareo-bicarbonated, and chalybeate.

There are two springs, the *Source Saint-Léger* and *Source Bert.*

According to Dr. Vintras ("Mineral Waters of France") the first, "which has been the longest known, supplies a very comfortable hydro-mineral establishment, to which it furnishes more than eleven thousand gallons of water per day. The second has been lately discovered, and is exclusively used for drinking. It is weaker than the *Saint-Léger*, and is rather an excellent table-water than a medicinal agent. The water of both springs is exported in very large quantities. The establishment is composed of a main building with two wings, one reserved for ladies, the other for gentlemen. It contains twenty-six baths, very complete douche arrangements, and everything necessary for hydrotherapeutical treatment."

ACCESS.—Five hours from Paris, on the Paris, Lyons & Mediterranean Railroad.

ANALYSIS.—According to Prevot, one thousand grammes of the *Source Saint-Léger* contain:

	Grammes.
Carbonic acid, free	0.6091
" of the bicarbonates	1.0098
" of the carbonates	1.6033
Hydrochloric acid	0.1275
Sulphuric acid	0.1450
Silica	0.0150
Peroxide of iron	0.0146
Lime	0.7000
Magnesia	0.1150
Potash	0.0450
Soda	0.6290
	4.4133

INDICATIONS.—The waters of this spa are used with benefit in cases of atonic and neurotic dyspepsia, gastralgia, lithæmia, gouty manifestations, gravel, diabetes, Bright's disease, and genito-urinary disorders, as well as the various morbid conditions depending chiefly on anæmia. In many forms of diseases of women they are said to be highly efficacious, a circumstance probably entirely due to their tonic properties.

The method of treatment at Pougues is chiefly by drinking the waters in moderate quantities, the baths, massage, etc., being merely used as accessories to the internal use of the springs.

ACCOMMODATION.—The hotels are comfortable and clean. The *Hôtel Splendide* is the best known establishment. *Edmund C. Wendt.*

PRESTE (LA). A spa in the Department of the Pyrénées Orientales, France.

LOCATION.—The little village of La Preste is picturesquely built on a small plateau not far from Amélie-les-Bains and Perpignan. The springs supply a hot sodio-sulphuretted water, used both internally and for baths. Some recent improvements have brought the thermal establishment up to modern requirements, and all the different douches, springs, etc., are now administered. The climate is pleasant and the surroundings agreeable. Vegetation is luxuriant.

ACCESS.—By the South of France Railroad to Perpignan. Thence in four and a half hours by carriage to the spa.

ANALYSIS.—The numerous hot springs seem to have a common origin and composition. The *Grande Source*, or *Source d'Apollon*, is alone employed. According to Anglada one thousand grammes of the water contain:

	Grammes.
Carbonate of soda	0.0397
" potash	traces
" lime and magnesia	0.0011
Sulphide of sodium	0.0127
Sulphate of soda	0.0206
" lime	0.0007
Chloride of sodium	0.0014
Silicic acid	0.0421
Barégine or glairine	0.0103
Loss	0.0051
	0.1337

Dr. Vintras ("Mineral Waters of France") says that the *Grande Source* rises within the establishment which it supplies, and furnishes forty-four thousand gallons per day of clear, colorless water, with a slightly sulphurous smell and an alkaline flavor. It deposits white filaments of *glairine* in the reservoirs. Its temperature is 113° F.

INDICATIONS.—The author above mentioned speaks as follows on this point: "It results from this analysis that the waters of La Preste are of a mixed character. They are sodio-sulphuretted and sodio-bicarbonated, and contain an excess of alkaline principles. They are employed for drinking, and for baths and douches. They are easily absorbed by the stomach, increase the appetite, and exercise a remarkable action upon the urinary passages, increasing considerably the secretion of the kidneys, and diminishing the over-acidity of the urine. They are also especially valuable to patients suffering from uric and phosphatic gravel, vesical catarrh, vesical irritability or spasm, and chronic cystitis. In these last cases they are superior to the strong sodio-bicarbonated waters. They facilitate the expulsion of renal calculi; they exercise also a beneficial action in chronic affections of the liver. In addition to the above, the waters of La Preste will be found beneficial in the cases for which ordinary sulphurous waters are prescribed, such as, for example, bronchitis and chronic laryngitis, idiopathic or spasmodic asthma, phthisis in the first stage, and certain affections of the skin."

The waters of this spa are now exported in large quantities, and are said to keep well.

ACCOMMODATION.—The thermal establishment is comfortable, the hotels are only moderately good, and the lodging-houses decidedly inferior. La Preste is much frequented, especially by Spaniards. The season extends from June to October. *Edmund C. Wendt.*

PROGRESSIVE MUSCULAR ATROPHIES. Our knowledge of the progressive muscular atrophies has begun to clear, but the entire subject is still involved in a dense mist of obscurity. While it may be well, for clinical purposes, to retain the classification proposed in the original article of the HANDBOOK, it seems to be pretty well established that all the different forms of the disease of muscular origin are mere varieties of a single genus, in fact, that they constitute esseutially the same disease. This is shown not alone by the numerous transitions from one form to the other, and by the fact that in many cases it depends merely upon the personal bias of the observer whether the case shall be included under one class or another, but by the further fact that the anatomical changes in the muscles are essentially the same in all the different varieties. It is well to remember in this connection that, according to Lewin, who has made a number of very thorough and interesting examinations of the muscles, the microscope furnishes no thoroughly reliable differential data between myopathic progressive muscular atrophy and pseudo-hypertrophy, on the one hand, and the muscular atrophies of undoubted nervous origin, on the other hand. Lewin's investigations have led him to believe that progressive muscular atrophy is a diffuse process, affecting the entire muscular system. The nuclear proliferation, which is such a prominent part of the process, is the initial stage of the disease, and is probably the expression of a reaction of the muscular tissue to some irritant. The latter may possibly consist of some substance circulating in the blood, or it may be due to the loss of an inhibitory influence on the part of the trophic centres. Erb is inclined to favor the latter opinion. He believes that myopathies are spinal in origin and due to a dynamic disorder of the trophic cells of the anterior horns of the spinal cord. He also believes that our present microscopical technique is unable to reveal these changes. The arguments which he adduces in favor of this theory are—the very prominent influence of heredity in the production of the disease, the localization of the atrophy in muscles which correspond to definite spinal centres, the frequent coincidence with idiocy, epilepsy, etc.

The arguments adduced are, however, insufficient to sustain this theory. There is no reason why heredity should not play a part in the etiology of diseases of the muscular system. The latter possesses a relative autonomy for embryological reasons, and is accordingly able to transmit its vices by heredity. Furthermore Babinski and Onanoff have shown that the distribution of muscular atrophy is related to the development of the muscles rather than to localization in spinal centres. The coincidence of muscular atrophy with nervous diseases of various kinds is also not a proof of the nervous origin of the former. Vices of evolution, due to hereditary taint, may affect various systems, and it is for this reason that progressive muscular atrophy may be associated with anatomical and dynamic changes in the nervous system as well as in other organs of the body.

Struempell propounds a very remarkable theory, which is based upon the clinical history and post-mortem findings in a single case. In this case there was an absence of degeneration reaction and of fibrillary twitchings in the affected muscles, so that despite the fact that the localization of the disease pointed very strongly to its spinal origin, Struempell was inclined to place it among the progressive muscular dystrophies. At the autopsy, however, extensive changes (atrophy) were found in the motor cells of the anterior horns of the spinal cord, and to a less extent in the peripheral nerves. The muscles presented simple (non-degenerative) atrophy. According to this writer the entire process begins in the muscles, and extends subsequently to the nerve-fibres and cells. After the muscular fibres belonging to a "neuron" (nerve unit, consisting of a nerve-cell and its fibre) have undergone simple atrophy, the entire neuron will be destroyed. This theory seems to us to be entirely disproved by the fact that the spinal cord is rarely affected, and that, furthermore, the lesion in the muscles is rarely due to simple atrophy.

Further light has been shed upon the condition known as the peroneal or leg type of progressive neurotic muscular atrophy, according to Hoffmann. This writer now proposes the term progressive neural muscular atrophy. The disease does not always begin in the lower extremities, but sometimes starts in the upper limbs, or it develops in both at approximately the same time.

In two cases Hoffmann detected abnormal electrical reactions of the facial nerve, the mimetic facial muscles, and the tongue, although the function of these parts appeared to be entirely normal. In a very carefully observed case Dubreuilh found old changes in the nerves. These changes diminished in intensity from the periphery toward the centre, and were barely indicated in the anterior cervical and lumbar nerve-roots; there was slight proliferation of the neuroglia in the columns of Goll, involving the entire posterior column in the lower dorsal cord. The gray substance of the spinal cord was normal. The changes were most pronounced in the nerves and muscles of the hands and feet. Hoffmann thinks it probable that the changes in the nerve are degenerative in character rather than inflammatory.

Our knowledge of the subject is still too meagre to warrant any positive satisfactory conclusions concerning the pathology of these conditions. But it seem to us that the constant drift of the new data—clinical and anatomo-pathological—which have been acquired within the last ten years, tends toward the view that the entire group of progressive muscular atrophies belongs to a single class of developmental anomalies, due to inherited embryological changes. The differences in the clinical history and pathology of the various forms included in this group depend upon whether the degenerative or nutritive changes affect primarily the muscles, the peripheral nerves, or the motor cells in the anterior horns of the spinal cord. Such a theory, if substantiated, would shed light upon much that is obscure in the relations of the different affections included under the head of the progressive muscular atrophies. *Leopold Putzel.*

PROLAPSUS UTERI. ANATOMY.—Under this heading it is proposed to consider certain points in the pelvic anatomy which have especial bearing on the subject of prolapsus uteri.

The bony and ligamentous framework of the pelvis fails to give complete support to the pelvic and abdominal viscera. A large outlet is required for the passage of the child; and through this same outlet the viscera tend to fall. The structures which close in this opening and

support the superincumbent weight must be strong, elastic, and dilatable.

The greater part of the uterus projects into the pelvic cavity and is freely movable. It must be classed among the viscera tending to fall through the outlet; and is, therefore, in part, at least, restrained by the same force as that opposed to the rest of the abdominal mass. In other words, the occurrence of a prolapse of the uterus involves the giving way not only of the structures whose especial function is the support of the uterus, but also of those which support the viscera above.

Looked at from this broad point of view, the term prolapsus uteri becomes too narrow in its meaning, and Hart and Barbour's expression, "Sacro-pubic hernia," is more apt.

The supporting diaphragm which covers in the pelvic outlet has been termed the "pelvic floor." Its structure is as complex as its varied functions would seem to demand, and many of the details are yet in need of investigation. In a general way, however, enough is known of both structure and mechanism to be of material aid in explaining the phenomena of prolapse, and indicating the line of treatment to be followed.

In describing this structure, for our purpose it will be convenient to start with the recto-vesical fascia. This is a diaphragm of fascia, concave above, attached to the pelvic wall along a line running from the lower border of the pubes across the obturator fascia to the iliac spine; thence across to become continuous with the lower part of the fascia of the pyriformis.

This diaphragm is perforated by the rectum and va-

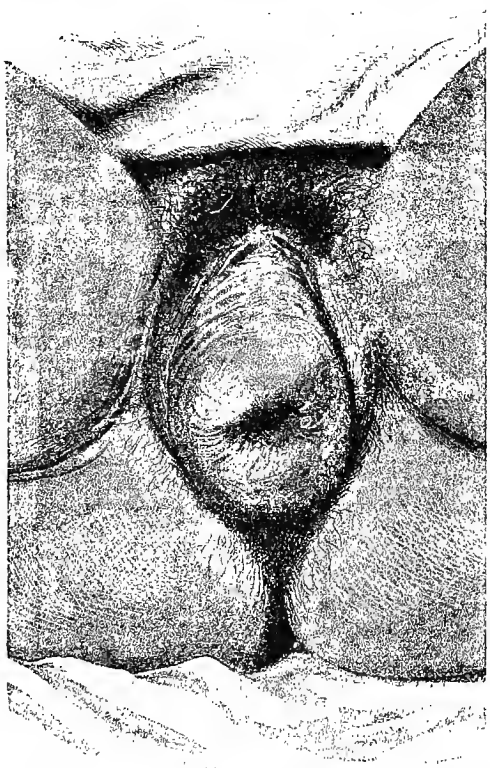

FIG. 539.—From a Photograph of Extensive Prolapse, with Hypertrophy of Cervix and Cystocele (Pozzi).

gina; and fibres are sent from the fascia to invest and strengthen the walls of these two canals. Portions of this fascia are especially strong and contain involuntary muscle-fibre. Most marked are the two bands running from the base of the bladder to the pubes—the anterior true ligament of the bladder. Less marked are the lateral ligament of the bladder and the ligament of the rectum.

Just beneath this concave sheet of fascia, and in close relation with it, comes another of muscle, the levator ani. The fibres take their origin along a line just beneath that of the recto-vesical fascia as far as the spine of the ischium. The fibres from the pubes pass down and back, separating for the urethra and vagina, part meeting in the median line, part mingling with the fibres of the ex-

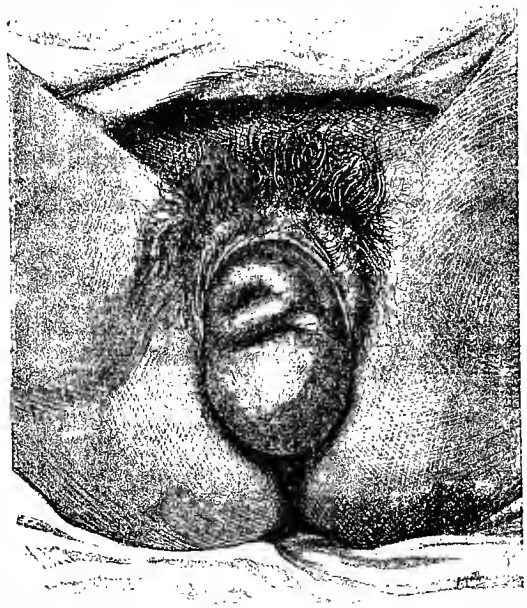

FIG. 540.—Extensive Prolapse, with Hypertrophy of Cervix and Rectocele (Pozzi).

ternal sphincter in the perineal body. The lateral fibres from the obturator fascia and spine of ischium converge as they descend upon the side of the rectum; while others meet in a median aponeurosis between the rectum and coccyx; the most posterior of all are inserted along the lateral margin of the lower part of the coccyx.

The whole muscle thus forms a diaphragm pierced by the vagina and rectum, and with the overlying fascia forms a concave floor upon which the abdominal and pelvic viscera can find support. Moreover the contraction of the levator ani will tend to lessen the concavity of this floor, and so raise the abdominal and pelvic viscera. It will also draw the lower end of the rectum up and forward; and, owing to the oblique direction in which the axis of the vagina is crossed by the fibres they will constrict this canal.

Before going further with the description of the supporting structure it will be well to consider a few points regarding the direction and relations of the three canals —urethra, vagina, and rectum. The urethra lies close to the subpubic ligament. The vagina has the lower part of its anterior wall in close relation with the urethra, and is bound firmly to it. The vaginal canal (which, it should always be borne in mind, is a mere transverse mucous slit in the pelvic floor) runs back and up at an angle of about sixty degrees to the horizon in the upright subject. In the upper part of its course it is in close relation with the rectum; but at a point about one and a half inch from the lower end the rectum turns suddenly back at right angles, so that its external orifice, the anus, is one and a half inch from the vaginal orifice. The tissues filling up this space between the two canals form the perineal body.

The thick, powerful, external sphincter ani, which has one origin at the coccyx, after passing about the anus, terminates in this perineal body, its fibres frequently decussating with those of the levator ani, bulbo-cavernosus, and transversus perinei muscles. The levator ani has already been described. The transversus perinei muscle

Prolapsus Uteri.

arises on either side from the tuberosity of the ischium, and meets its fellow in the perineum. The bulbo-cavernosi, which have little interest in this connection, come on their way along either side of the vulva, and meet again in the perineal body.

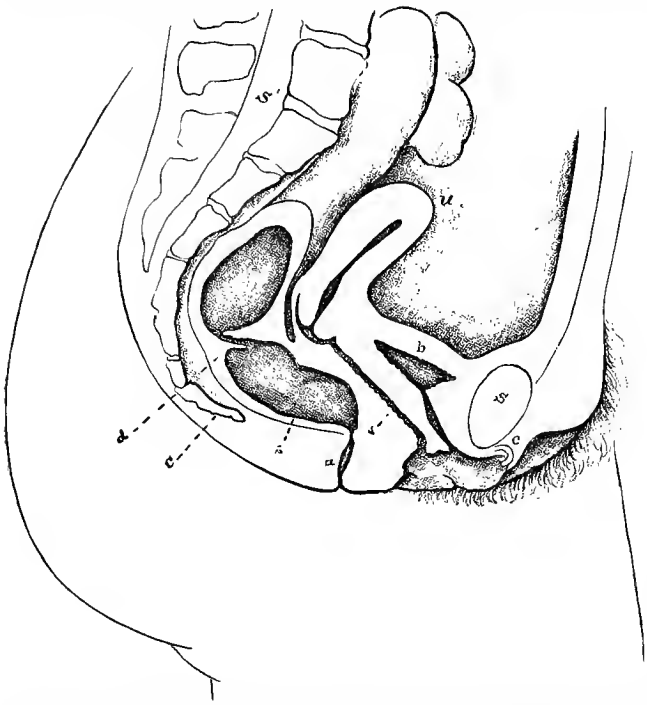

FIG. 541.—Sagittal Section, Median Line (Diagram). Shows relation of peritoneum to pelvic viscera, and the average position of the pelvic organs. *S*, Symphysis pubis; *S'*, sacrum; *c*, coccyx; *a*, anal canal; *r*, on perineal body, points to rectum; *v*, vagina; *e*, clitoris; *b*, bladder, when collapsed; *u*, uterus; *d*, valves of rectum (Ranney, modified from Foster).

The pubic triangle anterior to the transversus-perinei is closed in by a complicated fascia, the detailed description of which is unnecessary here. The important points are that although much weakened by the extensive longitudinal opening of the vulva it offers considerable support to the structures above; and its posterior fibres are fused with the substance of the perineal body. The deeper layer is in close relation to the under surface of the levator ani.

The perineal body, besides containing the structures mentioned, has a large amount of elastic fibrous tissue. It thus forms an important structure, a kind of *point d'appui* for all the muscles and fasciæ which bridge the pelvic outlet. From its position it supports the lower end of the anterior wall of the rectum, as well as the lower part of the posterior vaginal wall; while the anterior vaginal wall must receive support, as it is really above and resting upon the posterior.

There remains to be mentioned a considerable space back of the vagina, roofed in by the levator ani, and between the rectum and obturator fascia. This is the ischio-rectal fossa, and is filled with fat. Behind and somewhat below it is bounded by the inferior border of the glutæus maximus; the integument and superficial fascia on either side of the anus form the floor. This fat, resting on the structures named, gives some support to the pelvic diaphragm, and in its turn is helped (in the upright posture) by the pressure of the gluteal masses; while the region anterior to the perineum is supported by the crowding in of the large labia majora by the thighs.

To summarize briefly, then, we have a diaphragm of fascia and muscle supported to some extent anteriorly by deep perineal fascia, resting posteriorly on the ischio-rectal fat; while the bridge of muscles and fasciæ which meet in the perineal body forms with the integument the lower layer of the pelvic floor. The whole receives additional support from the fat of the buttocks, thighs, and labia.

The integrity of this floor is impaired by its perforation in two places: 1, by the rectum; 2, by the vagina.

Above the perineal body, for a variable distance, the vagina and rectum are in contact, though loosely bound together. As a rule the upper one-fifth of the vagina is free—the peritoneum of Douglas's pouch intervening. The anterior wall, which is shorter, is firmly attached to the urethra, but loosely to the base of the bladder. The upper end of the vagina is firmly attached to the cervix uteri. The axis of the uterus is forward, and nearly at right angles with the vagina. Posteriorly it has no attachment to the rectum; anteriorly it is loosely attached to the bladder, to about the level of the internal os. The bladder is loosely attached to the pubes, being separated from it by a mass of fat.

We now come to one of the most important of the intrinsic uterine supports—the sacro-uterine ligaments. From either side of the cervix a band of musculo-fibrous structure runs back, and out, and up, to be inserted upon the second bone of the sacrum. The fibres of this

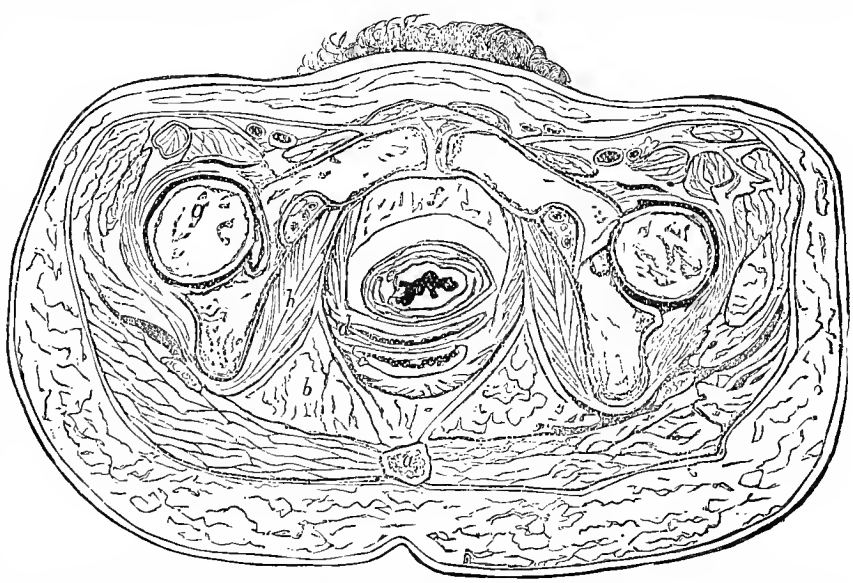

FIG. 542.—Transverse Section at Plane of Hip-joints (Ruedinger). *a*, Coccyx; *b*, ischio-rectal fossa, bounded by glutæus, obturator internus, and pelvic fascia; *c*, rectum; *d*, vagina; *e*, bladder; *f*, retro-pubic fat; *g*, hip-joint.

ligament are intimately united to the anterior wall of the vagina. In this way is formed a supporting beam for the uterus running from sacrum to pubes (Ranney).

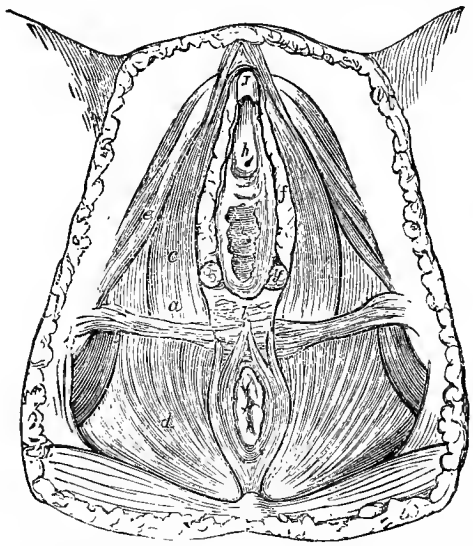

FIG. 543.—Dissection of Perineal Region (Savage). *a*, Just above transversus perinei; *b*, perineal body, junction of superficial perineal muscles; *c*, bulbo-cavernosus; *d*, on levator ani, in ischio-rectal fossa; *e*, erector clitoridis; *f*, bulb of vagina; *g*, Bartholinian gland; *h*, vestibule; *J*, glans clitoridis.

It now remains to speak of the broad and the round ligaments, and the pelvic peritoneum. The relations of the latter to the normal pelvic organs are too well known to be considered here in detail. It is important to note, however, that the peritoneum is exceedingly elastic, and

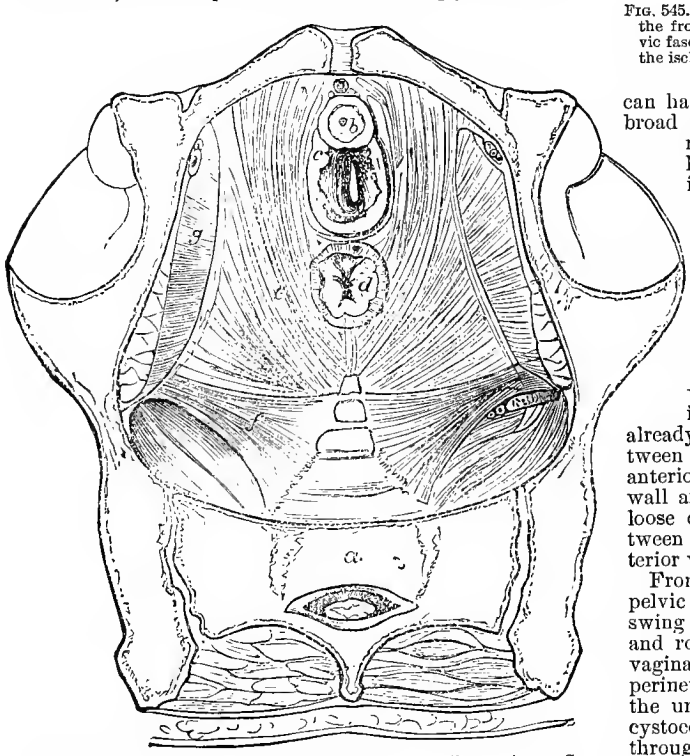

FIG. 544.—Dissection of Pelvic Floor from Above. (Savage.) *a*, Sacrum; *b*, urethra; *c*, vagina; *d*, rectum; *e*, levator ani; *f*, coccygeus; *g*, obturator internus.

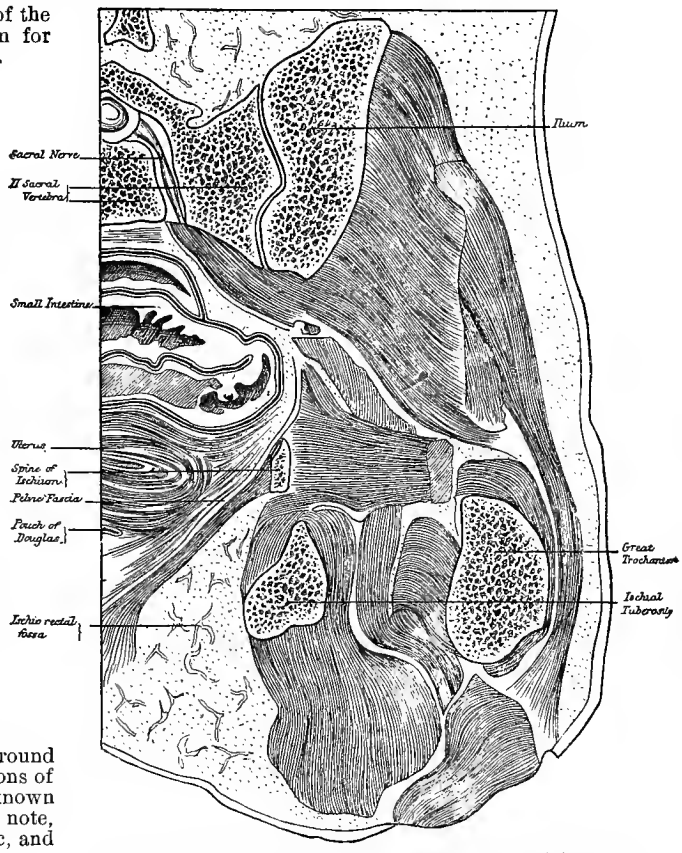

FIG. 545.—Coronal Section of Left Half of Pelvis. (Barbour.) (Seen from the front. The uterus was retroverted.) Shows the relation of pelvic fascia to levator ani which lies just below, and is seen rising from the ischial spine, also the cushion afforded by ischio-rectal fat.

can have very little power as an organ of support. The broad ligaments derive their strength chiefly from the muscular and connective tissue and vessels which lie between the layers of the peritoneum connecting the side of the uterus with the pelvic fascia. Their function is usually that of guy-rope rather than support. In extreme degrees of prolapse, however, they furnish considerable resistance. The round ligaments, in like manner, have practically nothing to do with the support of the normal uterus; and prolapse must be considerable before they are called upon to bear any strain.

The firm or loose nature of the connective tissue which binds together all the pelvic structures has importance in the mechanism of prolapse. As already stated, there is comparatively firm union between pubes and urethra; between urethra and lower anterior vaginal wall; and between the lower vaginal wall and rectum through the perineal body. There is loose connection between pubes and the bladder; between bladder, vagina, and uterus; and between posterior vaginal wall and rectum.

From this it follows that pressure from above upon the pelvic floor anterior to the broad ligament will tend to swing the structures anterior to the vaginal fissure down and round the pubes as an axis. So that the anterior vaginal wall would slide over the posterior wall and perineum, and protrude from the vulva, carrying with it the urethra and posterior wall of the bladder, causing cystocele. The pressure posterior to the broad ligament, through Douglas's pouch, would roll the upper part of the posterior vaginal wall forward and down. At the same time the uterus would descend, its axis following

that of the pelvic cavity. A rectocele is of comparatively rare occurrence, the posterior wall usually freeing itself from the rectum and prolapsing without it. Winkle speaks of one hundred and eight cases of pro-

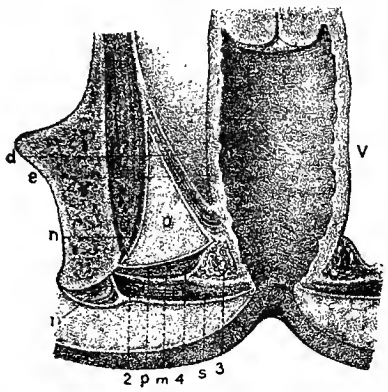

Fig. 546.—Perpendicular Antero-Posterior Section of Pelvis through the Vagina. (Savage.) *P*, body of pubic bone; *V*, vagina; *d*, recto-vesical fascia and the obturato-coccygeus muscle; *e*, inferior fascia of the same; *p*, posterior aponeurosis of the perineal septum; *m*, anterior aponeurosis; *s*, under layer of superficial perineal fascia; 1, sheath of deep layer of superficial fascia for the crus clitoridis and its erector muscle; 2, superficial transverse perineal muscle; 3, bulb of vagina; 4, lower muscular fibres of perineal septum.

lapse of the uterus, of which fifty-four were associated with cystocele; rectocele was found, however, in only thirty-three cases.

The peritoneum usually becomes displaced with the uterus, and occupies relatively the same position that it did with the uterus normally situated in the abdomen. This relation of the peritoneum to the prolapsed organ should be carefully studied.

From the foregoing it is evident that a prolapsus is complicated. No one structure is always primarily at fault; and it is as great folly to assign all cases to want of support in the perineal body, as to laxness of the recto-

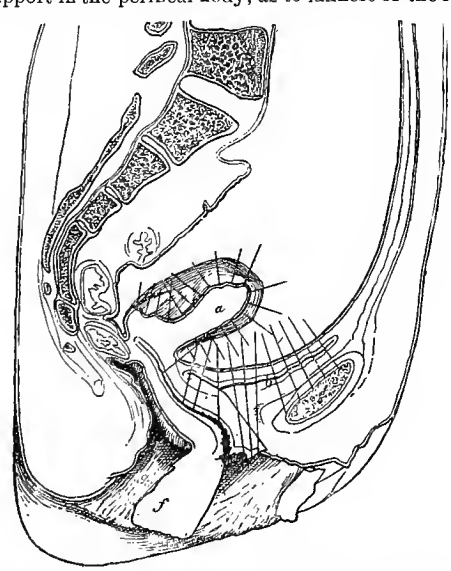

Fig. 547.—Diagram to illustrate effect of intra-abdominal pressure on the segments of the pelvic floor. (Hart.) *a*, Uterus pathologically anteflexed; *b*, bladder; *c*, rctro-pubic fat; *d*, labium majus; *e*, symphysis; *f*, perineal body; *g*, rectum.

Note tendency of pressure to displace downward all that portion of the pelvic floor in front of the anterior rectal wall.

vesical fascia, or utero-sacral ligament. All the supporting elements work together, so that failure of one throws undue strain upon the rest; and while ligaments and fasciæ and perineal body are important, we must not lose sight of muscular tonicity, abundance and quality of fatty tissue, and firmness of connective tissue.

Etiology.—Many points in the etiology have necessarily been considered in the anatomy.

The causes of prolapsus uteri, aside from the deformed pelvis, may be classed under two general heads: 1. Where the support is insufficient to bear even the normal uterus and viscera.

2. Where there is abnormal strain upon the pelvic floor and uterine support.

1. Under the first head, the injury to the pelvic floor during parturition is of prime importance. The ligaments and fasciæ have all been stretched; there is often rupture of the fibres of the pelvic fascia and levator ani. The perineal body is frequently torn transversely, laterally, or in the median line.

Where there has not been actual rupture there may be incomplete involution, leaving everything stretched, lax, yielding.

When there has been rupture it is easy to understand the natural sequence. With the integrity of the perineal body gone, many of the important structures in the

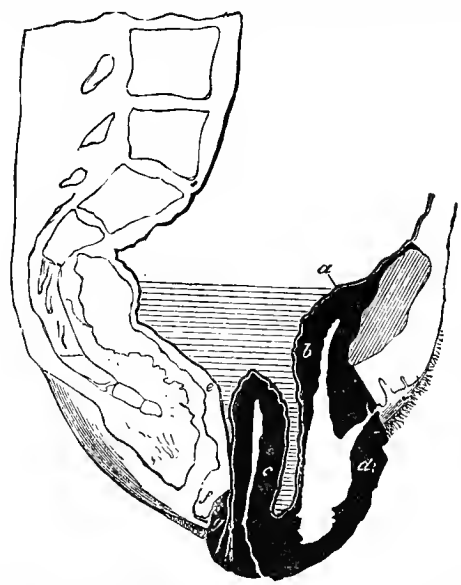

Fig. 548.—Diagram showing the result of intra-abdominal pressure causing prolapsus with cystocele, and illustrating the hernial nature of prolapsus uteri. *a*, Peritoneum; *b*, bladder; *c*, uterus; *d*, anterior vaginal wall; *e*, anterior rectal wall; *f*, perineum; *g*, posterior vaginal wall. (After Schütz.)

pelvic floor have lost their central point of support, or rather fixation. While if the laceration is such as to split the perineal body from before back, the posterior vaginal wall loses its support, and with the anterior rectal wall, tends to roll out through the elongated and probably gaping vulva. At the same time the anterior vaginal wall and the bladder, which naturally rest upon the posterior vaginal wall, lose part of their support, and tend to fall out also. These conditions, as is well known, are favorable to sub-involution of the vagina, and a prolapse of the lax and heavy vaginal walls is still easier. Under these conditions there is constant traction on the uterus by structures which should naturally tend rather to support it, or at least not to drag upon it.

Aside from the laceration and lax condition due to parturition, there may be incomplete support owing to loss of fat, or to want of tone in the muscular and ligamentous elements due to debility from any cause, such as disease, want of nourishment, and old age. Masturbation is also credited with bringing about a want of tone in the muscular and fibrous structures. Pessaries which stretch the vaginal walls play some part in impairing the support.

2. Under the second head (of abnormal strain upon the pelvic floor and uterine support) come all uterine tumors and others which are free enough to descend and bear upon the pelvic floor. The large sub-involuted uterus may be important, though it must be remembered that the sub-involution of the uterus is usually associated with a similar condition of the other pelvic structures which have been altered during pregnancy; hence the supports are lax and yielding at the same time, while the vagina is heavy and large and tends to prolapse.

Ascitic fluid may also aggravate any tendency to prolapse, though it is doubtful whether alone it would be of importance.

Hypertrophy of the cervix has sometimes been classed with prolapsus uteri. It may cause a prolapse by the increased weight; but it frequently exists in a marked degree, the cervix even protruding from the vulva, without causing any dislocation of the uterine body. Hence it should be classed under a special heading.

Tumors of the vaginal wall may cause enough dragging to dislocate the uterus.

Prolapse has been known to follow a blow on the abdomen, or a sudden severe strain, even in the virgin; and the frequent straining from chronic cough, constipation, stricture of the rectum, and strangury from any cause may be a serious factor in bringing about or greatly increasing prolapsus. It has long been well known that tight lacing is a frequent cause of this condition, and it becomes far more serious when there is constipation, cough, etc., in addition; the firm resistance of the abdominal wall throwing all the brunt upon the pelvic diaphragm. The age at which prolapse is found coincides nearly with that of the child-bearing period, as would be expected; though it may occur at any age and in a virgin. Munro reports a case in a child three years of age. Cases of congenital prolapse have been spoken of, but are not described with sufficient detail.

Out of 184 cases collected by Wanbey, there were only 6 occurring in women who had not had children. Winkle thinks that most cases of prolapse occur between the twenty-fifth and thirty-fifth years of life.

A deformed (kyphotic or spondylitic) pelvis may be the initial cause of prolapse. In this case the uterus does not find space sufficient for its accommodation. Veit reports the case of a girl, fourteen years of age, who had a kyphotic pelvis and prolapse of the uterus.

Diagnosis and Symptoms.—The diagnosis of prolapsus uteri is usually an exceedingly easy matter. All uncomplicated forms where there is prolapse to any extent, are self-evident. The cases which present difficulty are those where the degree of dislocation is slight; and these derive their importance from the fact that the symptoms may be wholly disproportionate to the apparent trouble, and the relief proportionately great from prompt and well-directed treatment.

Subjective symptoms which are in any sense pathognomonic do not exist, since the symptoms of this affection in its milder form are common to many other pelvic troubles. The displaced organ, by dragging on its support, by pressure on sacral nerves or rectum, and dragging on the bladder, and by interfering with the pelvic circulation owing to the twisting or pressure of the broad ligament vessels, will cause many symptoms which will call attention to the pelvis without indicating the exact nature of the trouble.

The commoner symptoms are pain (often dragging) in the loin, groin, and lower back; pain in the hip or thigh, constipation, painful defecation, frequent micturition, hæmorrhoids. As a result of passive congestion there may be leucorrhœa, dysmenorrhœa, menorrhagia, and metrorrhagia. Where the prolapse is excessive with protrusion of the cervix, or even of the whole organ, the constant irritation from exposure, rubbing, and dribbling of urine (a common feature of this condition) will cause ulceration of the mucous membrane, and hence pain and discharge.

It is evident then that the diagnosis must rest upon vaginal examination. As a rule, in the early stages the uterus retroverts as it descends; but this is not necessarily the case, and it is important not to be misled by this into overlooking the cases where there is a retrocession of the uterus toward the hollow of the sacrum, while it still maintains the normal angle with relation to the axis of the vagina. These cases are probably due to a relaxation of the anterior support, while the utero-sacral ligaments remain normal; and our experience would indicate that this condition is relatively more common in nulliparæ.

Since the uterus is normally so mobile, and since there is so much difference in individuals, it is practically impossible to define a limit which shall determine where prolapsus begins. In the slight cases the relief given by tentative treatment will be the criterion.

The condition most likely to be confused with prolapse of the uterus is hypertrophy of the cervix, particularly the forms where the intermediate or supra-vaginal portions are involved. Here the bimanual examination, and if necessary the passage of a sound, will show whether the fundus is still in the normal position.

The differentiation between prolapsus uteri and vaginal tumors, or fibroids and polypi extruding from the external os, will be easy if pains are taken to find the cervix and determine the position of the canal.

For practical purposes, however, the diagnosis of the existence of prolapse is the least important part of the examination. It is of much greater importance to determine the associated conditions, viz., the position and condition of ovaries and tubes, the presence and character of adhesions, the condition of the perineal body, the probable relations of the peritoneum, and the existence of true rectocele and cystocele. A sound in the bladder, and sound or finger in the rectum, will show whether the mucous membrane of these organs has prolapsed with the vagina.

Treatment.—To speak of treatment without first considering the prophylaxis of prolapsus uteri, is to ignore a most important factor in its production, namely, the improper management of cases during and after confinement.

All tears of the perineum occurring during labor should be carefully repaired, and the posterior vaginal wall inspected for any laceration which may extend along its surface. If such is found it should also be repaired.

The rectum should be empty by the second day; the bladder should never be allowed to remain full for any length of time after the first day; and the position of the patient should be changed from time to time. Rest in bed is of great importance so long as the uterus is large and heavy; and until involution is well established any laxity of the vaginal walls should be treated by the use of astringent injections and tampons. Large tears of the cervix should be operated upon as soon as possible after convalescence.

Treatment of prolapsus may be divided into palliative and surgical.

Slight degrees of prolapse can often be relieved, and sometimes cured, by the use of tampons or pessaries, but they should not be used soon unless the vulvar opening is intact, and then only when the uterus is moderately small and easily placed in its normal position. Ring pessaries and air pessaries are of very doubtful utility, because of the tendency they have to stretch the vagina and eventually make the condition worse than it was before their use. The stem and cup pessary with bulb and perineal band, may be indicated in very exceptional cases, but their clumsiness and filthiness will exclude their use in almost every instance. Hodge's pessary will often be found useful. Gehrung's pessary for cystocele is very difficult to adjust and should never be employed by anyone who does not thoroughly understand its application. Schultze's sled runner pessary may also be given a trial.

Brandt's method of pelvic massage has found some very warm advocates, and is of undoubted use in cases of prolapse where the supports below are moderately intact, where the uterus is small, and where the trouble probably arises from loss of tone in the uterine ligaments, with a lax and atrophied condition of the pelvic cellular tissue; also in cases complicated by adhesions.

The surgical treatment offers such a good chance of recovery, and is attended with so little danger, that it is to be insisted upon in the majority of cases.

The surgical treatment of these cases can, in a broad sense, be divided into four parts:

1. Operations intended to diminish the size of the uterus, and to close to a greater or less extent the vulvar opening.
2. Alexander's operation.
3. Operation for the ventral fixation of the organ.
4. Extirpation of the uterus.

Under the first heading must be mentioned amputation of the cervix, curetting and packing the uterus, the use of electricity, and later some plastic operation upon the perineum and vagina.

Alexander's operation is one of great use in properly selected cases. It should never be undertaken when the uterus is heavy or when the prolapse is complicated by any form of pelvic tumor, or by adhesions. The support from below must be good, and for this reason operations on the cervix and perineum should precede Alexander's operation. If these rules are observed satisfactory results will follow, and Alexander's operation will be found a most useful adjunct to operations on the uterus, perineum, and vagina.

Ventral fixation is a method of treatment having much the same limitations as Alexander's operation, and possesses no advantage over it provided the round ligaments can be found, except in certain cases where there are adhesions which might be safely broken up through the open abdomen, but which would be unsafe to tear by means of bimanual manipulation.

If the abdomen is opened for the removal of some pelvic growth complicating prolapse, then ventral fixation may be attempted or else some method of shortening the round ligaments within the abdomen, as by folding them on themselves or uniting them in front of the uterus.

Vaginal and abdominal hysterectomy have been undertaken for the cure of prolapsus. The technique is the same as when the operation is performed for fibroids, or malignant disease; and as yet a sufficient number of cases have not been collected to warrant an opinion regarding its utility. This much, however, may be said, that in some few cases herniæ have developed into the vagina, which naturally made the condition of the patient more pitiful than before the operation.

Resort to operative measures should never make the surgeon unmindful of the importance of general and local tonic treatment. Good general health and muscular tonicity, with a healthy condition of vaginal mucous membrane and endometrium, will increase the power of the supports and diminish their burden, thus making the results of operative treatment more satisfactory and enduring.

George Haven.
George A. Craigin.

PROPHYLAXIS, GENERAL PRINCIPLES OF. Medicine as an art finds its highest point of development and practicability in the prevention of disease. The process of prophylaxis has been from the empirical to the rational, though, as a completed science, it still remains far short of a perfect system. Its principles, like all great truths that affect the welfare, progress, and destiny of mankind, have long been foreshadowed in beliefs, superstitions, and vague conceptions, and instinct has often served as a guide where reason failed to discover. Indeed the notion that disease is avoidable and preventable, may be said to be primitive, if not innate in the human mind, being manifested in some form or other among all nations and races during all times. The ancients possessed it, and from the very earliest dawn of medicine until now, the search after absolute and specific preventives of disease has always occupied a large share of the attention of those engaged in the practice of the art. The Egyptians, the Greeks, and the Romans recognized the great importance of sanitation and hygiene as prophylactics, and inculcated rules for the preservation of health and the prevention of disease. Moses, the lawgiver, laid down a sanitary code, with severe penalties attached for infringement, and gave special direction for the disinfection of persons, places, and things, so thorough and effective in use that even this advanced age can find but little room for improvement. Among the Orientals the amulet is the most ancient form of disease preventive. Thus a dried toad worn next to the skin was held to be a protection against the plague, and coral worn by infants was supposed to preserve them from all the diseases incident to teething. Many of the precious gems were held to shield their possessors from the effects of poisons, or even to betray their presence by change of color when brought near them. The diamond and amethyst were reputed to guard against drunkenness. So lately as 1808 the Shah of Persia thought that he could not send a more acceptable present to Bonaparte than a few of the precious bezoar stones, which that great man, however, did not appreciate at their Oriental value, for, it is said, he contemptuously threw them all into the fire. Pope Adrian used an amulet composed of dried toad, arsenic, pearl, coral, emerald, tormentil, hyacinth, and tragacanth. Serapion recommends the gem hyacinth as an excellent amulet to protect the body during thunderstorms. The ancients made use of the *lapis lazuli* as an amulet, and Schröder describes it as an admirable charm for driving away fright from children. In the time of Queen Elizabeth, of England, we find Lord Chancellor Hatton, writing to Sir Thomas Smith, saying, "I am likewise bold to recommend my most humble duty to our dear Mistress (The Queen) by this letter and ring, which hath the virtue to expel infectious airs and . . . I trust, Sir, when the virtue is known, it shall not be refused for the value." In heathen countries the images and symbols of one or other of their gods were worn as amulets. When Christianity became triumphant the representation of its Founder on the Cross, and passages from Scripture, were used to ward off disease, or even the Evil One. Celsus says in the preface of his work, "De Re Medica," "Diseases are to be attributed to the wrath of the immortal gods, and from them relief is to be sought." These instances of superstition and credulity might be multiplied indefinitely. They are, however, sufficient to illustrate the general prevalence of the ideas and methods employed to prevent disease. Man, in every country and at all times, actuated by the first law of nature, shrinks from pain and gives faith and credence to the mysterious and incredible, if it only promise to shield him against danger or calamity. Not only is this true in respect to ancient and mediæval times, but even at this day we find peoples and communities, judged as intelligent in ordinary matters of life, resorting to, and relying upon, the protecting influences of little bags of sulphur, garlic, or camphor, hung from the neck, which they deem capable of warding off contagious disease. In contradistinction to these primitive and irrational conceptions modern prophylaxis undertakes to possess an actual knowledge of the real causes, and as an art seeks, through rational measures, to combat and destroy them. Its cardinal principle is knowledge of, and avoidance of, causes. Guided by these, its purposes are carried out by two methods in the attempt to prevent the occurrence of disease. The first of these undertakes to conform to the general rules of sanitation and hygiene, and thus bring the body into a vigorous condition of health; and the second aims to afford protection by investigating, understanding, and removing the predisposing conditions and causes of disease. From this conception it is evident that a completely developed system of preventive methods is possible, through an actual and exhaustive knowledge of the several and various elements of physiology, hygiene, and etiology. In the light of developments made possible through the achievements of the germ theory and cell doctrine of diseases, a science of prophylaxis has been rendered feasible and possible. In order to understand its principles and methods it will be necessary that a brief examination be made into those circumstances and influences which are ordinarily presumed to favor or retard the origin, development, and the distribution of disease. Many of the older conceptions of morbid phenomena have been entirely revolutionized by the advent of microscopy and bacteriology, and in no department is this change more marked and radical than in that of etiology.

In former times the latter was chiefly an *x*, which each speculator defined as he pleased, and a number of them did not fail to avail themselves of some of the most fanciful and wildest of guesses. We now know that many of these are false, and are furthermore enabled to form exact notions of the nature, origin, habitat, and *rôle* of the causes of disease, and to fully estimate their importance individually. Not only are our data concerning the exciting or proximate causes more ample and precise, but our knowledge of the predisposing conditions of disease and their power to produce susceptibility in the organism has been considerably extended in recent times.

It is now proper to take a cursory survey of these several factors of etiology and attempt to discover their nature and *rôle*, and assign to each its proper value in this connection.

The predisposing conditions of disease are found to exist in, and emanate from, internal and external human environment. All zymotic phenomena, while not originating in peculiar environment, so far as we now know, yet are its inevitable outcome. This is true to the extent that there must always be a pathogenicity upon the part of the germ, and a susceptibility upon the part of the individual attacked, or else there is no disease and the organism escapes. If either of these co-operants be absent or inoperant there is failure to originate morbid phenomena, and the germs are not reproduced. Hence, should there be anything in the media to hinder the conjunction and co-operation of both of these necessary factors, disease does not occur. Prophylaxis as a science undertakes to discover and understand these necessary conditions, and by modifying or avoiding them seeks to prevent their products—disease. In order to accomplish this, its procedures and methods partake of two general divisions. The first is to prevent liability or susceptibility on the part of the organism ; the second, to remove or destroy pathogenicity upon the part of the germ, and to render all circumstances and conditions which favor or foster its presence and perpetuation hostile. The first division of these methods is largely hygienic, sanatory, and preparative in character, while the second is aggressive and purposes to seek out and destroy the germs. In the latter we have the method of disinfection and antisepsis illustrated. Experiments show that when animals are well fed and cared for, and brought up to a high state of nutrition, they may withstand inoculation of viruses which under ordinary circumstances would destroy them ; and that the under-fed or half-starved are highly susceptible and quickly succumb. From experiments of this kind it has been found that susceptibility is invariably present in a directly inverse ratio to the standard of nutrition of the animal. In the light of these facts it is seen that the metabolic processes of the organism through which the functions of respiration, circulation, digestion, and assimilation are maintained, are highly essential to a competent degree of vital resistance. Hence we are led to believe from this standpoint that the prevention of disease will largely depend upon the attention paid to those methods which are connected with the nutrition and vigor of the organism in general, and the body-cells in particular. In this connection food, habitation, clothing, exercise, and ventilation stand paramount to all others. In their absence the organism cannot exercise its highest forces of protection, being deprived of the physical basis of energy, and the organism becomes susceptible and liable to invasion. Our success in combating morbid agencies will largely depend upon the degree of prominence given these details and the efficiency with which they are executed. They constitute the fundamental principles and ultimate grounds upon which to erect the edifice of a rational prophylaxis. They indicate the cardinal fact that disease agents do not possess the power of unconditionally deranging the health, but that there are certain conditions necessary for this, and that it is only when the organism is sufficiently predisposed to be susceptible that the germs can enter and set up disease. In further substantiation of this point, the luminous and far-reaching theory of Metschnikoff enables us to both appreciate and understand its importance. It furnishes us with a clear conception of the final details of the mechanism of the cells, whereby they resist and destroy the micro-organisms of disease. In another direction the equally important investigations in regard to the *rôle* and influence of the fluids of the body, such as the blood, glandular products, and intercellular-tissue juices show how the organism employs these as a means to resist disease ; and it has also been shown that the blood-serum not only exercises important properties as a germicide, but also furnishes, when of proper quality, the means for the subsistence and functions of the phagocytic cells.

Thus far we have viewed briefly those agents and agencies internal in the organism whereby it protects itself and maintains its integrity. It is now proper that we direct attention to a few of those conditions which tend to so alter and modify these as to render the system liable to disorder. The factors of race, age, sex, temperament, idiosyncrasy, heredity, and habit of body are all recognized as elements in the etiology of disease. Under present circumstances of our knowledge, prophylaxis has no means through which it can obviate or avoid the results of these causes, and it at best can only expect to modify their effects. No precautionary measures with which we are now acquainted are capable of entirely combating the influences emanating from these, and they must, from the nature of the case, be largely considered as inevitable in character. In the second division of predisposing conditions, such as follow from influences of climate, soil, habitation, occupation, class, and season, we do find them susceptible of modification and control, and we can so act as to ameliorate or completely counteract their deleterious effects to a large degree. It is with the latter that prophylaxis is chiefly occupied, and finds its field of usefulness. Without dwelling *seriatim* upon each of the above agencies, it may be said in a general way that climate, class, occupation, and food constitute the leading and most important predisposing causes of disease. Man, like all living organisms, is powerfully affected by the nature of his environment. Under certain circumstances the conditions of the latter are highly propitious and lessen the struggle for existence ; on the other hand, they may be antagonistic and render life precarious and hard. Again, in one respect, at least, the importance of heredity cannot be over-estimated. That is, we must distinctly understand that those predisposing conditions which exist by virtue of temperament or idiosyncrasy, also those typical proclivities called diathesis, however influential as factors controlling morbid processes in individuals, receive their force and character from heredity, and may be said to be merely effects of hereditary predisposition specialized in certain sets of individuals ; but heredity means much more than mere temperament, idiosyncrasy, and diathesis, for it not only includes all these, but also implies a morbid predisposition which has arisen in the ancestors before, and has been transmitted to the offspring and has become intensified by descent, or modified by sex, age, or accessory circumstances. We may not know what these intricate and occult conditions are, but we see them manifested as results concerning which there can be no doubt. In such disorders as gout, rheumatism, diabetes, scrofula, cancer, neuralgia, rickets, syphilis, epilepsy, chorea, and a number of others, the hereditary factor is frequently present and exercises a powerful influence. In respect to climate, the effects are potent. In the warmer or tropical countries of the earth the duration of life is shorter, and the morbidity and mortality greater than they are among those who live in temperate regions. In the colder regions these extremes are again met with, and disease is more frequent and deaths more numerous as the result of pulmonary and bronchial disorders. Thus within certain limits the dangers from warm and tropical climates are equal to those resulting from cold and dampness. In warm regions germs and their products, in the form of paludal fevers, are indigenous. Humidity and warmth, together with the large quantities of decaying vegetable substances incident to the tropics, afford a favorable culture medium for the perpetuation and existence of germs, and

the inhabitants are a ready prey. The association of pneumonia, bronchitis, rheumatism, and asthma with a bleak and wet climate is too invariable to permit our doubting their reality as causes. Sydenham attributed to the atmosphere an "epidemic constitution." Moist weather, be it hot or cold, is always found conducive to the spread of contagion. From this we can regard it as certain that there exists a connection between infectious disease and the atmospherical conditions. Statistics show that cholera, diarrhœa, and the exanthemata are always aggravated by damp weather. A warm, dry climate, on the contrary, tends to check or lessen the spread or progress of morbid agents of every kind. The ailments most usually associated with climate are those commonly regarded as inflammatory, and the exact value of its influence in prophylaxis has not been worked out except in a very general way. In respect to occupations as predisposing to disease, the fact of such predisposition is well known and admitted. The indications for prevention are plain and need not be dwelt upon here. The same is true of the influences arising from class. Poverty is a potent factor in undermining the organism through the want of food, clothing, and suitable habitation. Statistics show that the upper classes have a longevity twenty-five per cent. greater than the lower class, and fifteen per cent. greater than the middle artisan classes. In the matter of susceptibility to disease, Korosi, of Buda-Pesth, found that cholera, small-pox, measles, and typhoid fever were far more prevalent among the poor. Zymotic diseases as a whole were sixty per cent. more frequent among those living in basements than among those living in higher domiciles. In regard to other statistics of this class, those of Dublin show that in the first class of society, including independent people and professors, the mortality was 22.5 per 1,000. In the second, or middle class, it was 25.4 per 1,000. For the third class, composed of shopkeepers, workmen, and others, it was 26.1 per 1,000; while for the fourth class, occupants of jails, poorhouses, and those in the lower walks, it was 37.5 per 1,000. Influences emanating from city and suburban life show marked contrasts in producing liability to disease. The influences of city life tend toward degeneration and are highly conducive to disordered innervation leading to increased predisposition to disease. Its crowds, its dust, the deprivation of light and sunshine, filth, bad odors, bad water, and want of out-door exercise are potent causes of debility. This is true in so far that it is well-nigh impossible to find a fourth generation of pure bred Londoners or Parisians, their progeny dying out in early life, partly from physical and moral decline and partly from inability to continue the struggle for existence. The pure Londoner of the third generation can seldom be found in the workshop, for his physical condition is too poor to stand the strain, and he is, as a rule, short, narrow-chested, scrofulous, and with deformed jaws, and a small head. In the struggle for existence such men are at a disadvantage and succumb as the early prey of disease agencies. From what has already been stated in regard to the predisposing or debilitating influences of disease, their nature, kinds, and means of operation, the indications for their modification or removal are evident. The purpose of prophylaxis in this direction will be to produce a high state of bodily health through the means of hygienic and sanatory methods, and to remove or destroy those circumstances of environment, in so far as such a thing is possible. The preservation of health-giving conditions of any and all kinds is the great prophylactic principle. To augment and fortify the reserve forces which are manifested in the form of vital resistance to disease agents is the chief object. In combating the presence and maintenance of germs without the body, we have the second department of prophylaxis, which embraces the methods of antisepsis and disinfection. The purpose of these is to destroy the pathogenic agency of infectious material and thereby prevent the spread of disease. It may be stated that a disinfectant for one disease is a disinfectant for all, and what is capable of acting as a germicide for one, is capable of acting in others. Any agent, therefore, which in certain proportions acts as a germicide, in a smaller quantity may act as an antiseptic. An antiseptic is any substance capable of preventing or retarding the growth of the bacteria of putrefaction. It follows from this that all germicides are antiseptics, though all antiseptics are not germicides. The purpose of germicides is the absolute destruction of infectious agencies; on the other hand, antiseptics may be employed to prevent and arrest putrefaction, and thereby destroy the media upon which infectious agents may lodge and propagate. Collections of putrefying matter should be disinfected and removed, not because they promote and invite the presence of every form of bacterial disease, but because the effluvia and noxious odors arising from them are possible sources of debilitating influences, and in this way they operate directly upon the economy and render it more liable to the invasion of disease. The apartments of the sick should be freely ventilated. In most instances the uppermost room of the house is the best location for the care of a contagious disease. Here the patient will obtain freest access to air and light, and be less liable to be visited and seen by those who may be liable to contract the disease. When the malady subsides all bedding, carpets, hangings, furniture, and clothing should be submitted, as the nature of the article demands, to thorough processes of disinfection as hereafter described. For the disinfection of rooms and apartments chemical substances are used of a gaseous and liquid form. One of the best for this purpose will be found in chlorine. It decomposes hydrogen and ammonium sulphides at once, and is more certain than any other gas. Chloride of lime moistened with water or with dilute sulphuric acid, and placed in a shallow vessel, will furnish it from a ready source. It will destroy organic matter in the air. Another, cheaper, more efficient, and convenient disinfectant for apartments will be found in sulphur dioxide. To be efficient it must be used in large quantities. Ten pounds of sulphur moistened with alcohol, ignited in a closed room, should be allowed to burn for six hours to disinfect a space ten feet by fifteen feet by seven or eight feet. Fortunately for personal prophylaxis and disinfection, the actual seats of the germs in the body are known. In each particular disease there is always some particular part, tissue, or organ which is chiefly occupied by them. In employing disinfectants it is proper that we always begin with a direct special attention to these parts. In the exanthemata it is the skin and mucous membranes that constitute the leading centres for the production or propagation of the infectious agents, and they should receive the most attention. In diphtheria the same methods will apply, while in cholera, typhoid fever, dysentery, and diarrhœa, it is the discharges from the bowels and kidneys that demand the most scrupulous care, since it is by these avenues that they are reproduced and act as the vehicle for contagion. For personal disinfection of the skin and fauces, Labarraque's solution diluted with twenty parts of water, is useful and efficient. Oily disinfectant inunctions for the skin by means of carbolized sweet oil, vaseline, or camphorated oil are good, and furnish the best means of preventing the detachment of epithelia and pus; they should be employed from the very commencement of small-pox and scarlet fever. The throat in these diseases should also be washed freely with Condy's fluid, a weak solution of sulphurous acid and water, or Labarraque's solution. All discharges from the nose, lungs, and throat should be received upon rags and immediately burned, or, if upon towels or handkerchiefs, these should be at once plunged into a solution of chloride of lime. The body in these disorders may be also bathed or sponged with one per cent. solution of chloride of lime, weak carbolic-acid solution, or a 1 to 10,000 solution of the corrosive chloride of mercury. In those instances where the stools are the subject of apprehension, they may be disinfected with a solution of corrosive chloride of mercury, one half-ounce of the salt to a gallon of water, and clothing that is suspected should be treated by placing it in boiling water to which has been added two ounces of chloride of lime for each gallon. For the disinfection of apartments, clothing, bedding, carpets, hangings, closets,

sewers, and other places of contagion, there are other means at command. Among the most effective, convenient, and reliable of these may be mentioned moist and dry heat, and chloride of lime in solution. In addition to these we possess other agents of lower powers of disinfection which will be found suitable for ordinary antiseptic and deodorant purposes. These are boiling water, dry heat of a temperature of 180° F., sulphur dioxide, carbolic acid, sulphate of copper in solution, chloride of zinc, and sulphate of iron in solution. In regard to the first of the former list, heat, it is scarcely necessary to say that fire, complete combustion, is an effective method of destroying disease agents. In buildings of little value and in the case of articles of clothing and furnishings which have been infected with dangerous contagia, such as small-pox, cholera, or diphtheria, it is always the best and safest plan to destroy them by fire whenever the circumstances will allow. Heat, for general purposes of disinfection, is the most effective of all methods. It is employed in several ways both as dry and moist heat. Drs. Parsons and Klein have made numerous and elaborate experiments both in regard to the degree and the form of the heat, and in regard to the duration of the exposure. These tests show that dry heat is the best form and most readily adapted for the ordinary purposes of disinfection to which it is applied. This kind of heat can be supplied by means of a common laundry drying closet or a baker's oven, either of which affords a sufficiently powerful heat to destroy all contagious matter. The chief objection to dry heat is that it penetrates bulky and badly conducting materials very slowly, and the time usually allotted for the destruction of germs is far too brief for the complete destruction of all of them. If the drying closet be used care should be taken to let the articles remain exposed for at least four hours, and the temperature should not be below 200° or 250° F., the latter being far better. Ordinary fabrics such as linen, wool, silk, and cotton will bear a temperature of 200° F., without danger of being scorched. White woollens are always soonest affected, and should be carefully watched. To avoid bad effects the temperature should be observed carefully and never permitted to exceed 250° F. in any case. Dry heat is generally applicable to all classes of goods that can be boiled, and is said to be materially aided in its penetration by the addition of a certain amount of moisture, though the latter does not directly assist in the destruction of the contagia. Koch, from experiments, found that bacteria in general, free from spores—and no human disease with which we are acquainted possesses them—cannot resist a temperature of 212° F. for many minutes, and that if it be continued for an hour and a half they almost all invariably perish. Steam is considered to be the best form in which moist heat may be employed. Its complete penetration for five minutes is found to accomplish thorough disinfection. Koch, Parsons, Klein, and others are all agreed in their preference for it, because it is more rapid, certain, and reliable than any other agency. A pressure of twenty-five pounds, if continued for five minutes, will always insure complete penetration and the death of the bacteria. The results of the employment of boiling water are not shown by experience to be completely satisfactory. However, if the boiling process be kept up sufficiently long, say for several hours, and a little carbolic acid or chloride of lime or zinc be added to the water, the results can be relied on to a certain degree. If in any case there should be any doubt, when the disease is of a fatal character, the articles should, when such a step is practicable, be submitted to dry heat in an oven or drying closet, and the highest temperature compatible with the safety of the fabrics should be used. As a rule in these cases, the finest fabrics, such as linens, cottons, and woollens, may be treated to a temperature of 225° F. for an hour without apprehension.

With regard to the mode by which chemical disinfectants act and exert their influence as such, there are a number of speculations and solutions offered. Some are thought to act by oxidation, others by their properties of coagulating albumin, and still others in a manner quite unknown or but little understood. A number of the chemicals employed as disinfectants are known to evolve oxygen freely, and are presumed in this way to hasten the disintegrating of the noxious matters. Chlorine, nitrous fumes, and ferric compounds are supposed to disinfect by this process.

Bichloride of mercury in solution is the most powerful and reliable disinfectant known to science. Experiences show that it is a deadly poison to all the lower forms of life, which it kills almost instantly when employed in the proper proportions. In the proportion of one part to five hundred parts of water it destroys the vitality of bacteria in ten seconds; in the strength of one to two thousand, in one and one-third minute; and in that of one to twenty thousand, in from fifteen to twenty minutes. Thus it will be seen that time is an element always to be considered when the solutions are used in ordinary proportions. The fact that bichloride of mercury combines with albumin leads to the belief that it interferes somewhat with the process of destruction, and this is always to be remembered when it is employed. It cannot be used in connection with lead, tin, or copper, owing to its corroding properties, and for this reason it is not suitable for disinfecting vaults, sewers, or privies, where metal pipes are a part of the fixtures. The following solution is recommended by Sternberg as capable of destroying completely all the germs associated with infectious disease, viz.: bichloride of mercury, four ounces; sulphate of copper, one pound; water, one gallon. Dr. Parsons recommends the following solution as suitable for clothing, excreta, etc.: bichloride of mercury, half an ounce; hydrochloric acid, one ounce; aniline blue, five grains; water, five gallons. Mix. This is the standard solution No. 1, of the Public Health Association, and has been tested thoroughly as to efficacy. It should always be labelled "Poison."

Chlorine gas is another powerful oxidizing agent, and is extremely irritating to the air-passages when inhaled. It decomposes ammonia compounds and sulphuretted hydrogen, and affects all substances arising from putrefactive changes. It bleaches organic matters and destroys odors, either by withdrawing hydrogen or by direct oxidation. It is a pale, yellowish-green gas at ordinary temperatures, about two and a half times as heavy as the atmosphere. Chlorine gas is usually generated by means of chloride of lime, moistened with water or dilute sulphuric acid. There are several popular disinfectants which contain this gas in sufficient proportions to be of service in disinfection. Among these may be mentioned Platt's chlorides, Labarraque's solution, and Javelle water. Chloride of lime is frequently used without the addition of water or dilute sulphuric acid, being scattered over the surface of apartments or the earth, and in gutters, vaults, and privies, and the moisture in the air liberates the gas as free chlorine. Bromine and iodine gas are used for purposes of a similar character, but their expensiveness renders them impracticable for common use. In this connection it may be added that fumigation should always be regarded in the light of an accessory process, and that when infection is actually present, it should invariably be supplemented by the other and more efficient processes of baking with dry heat, steaming, and washing, as the exigencies of the case may require. A failure to do this and make the process complete will, through leaving a single article or place overlooked, create a new centre for infection, and the work will have been futile. All wood-work, walls, floors, and furniture must be rubbed down and washed with a solution of bichloride of mercury, an ounce to the gallon of water, and the hangings, bedding, and clothing submerged, or rinsed in a weak solution of chloride of lime. For purposes of fumigation the most available, inexpensive, and reliable antiseptic for apartments is sulphur dioxide (SO_2). This is the most ancient of all scientific agencies used for the purpose of preventing the spread of disease and destroying the lesser forms of life. The Greeks and Romans were acquainted with the preservative properties of this gas, and used it as an antifermentative in wine. Guyton de Morveau, who

first studied its action, was of the opinion that it would completely destroy miasms. Koch asserts that anthrax bacilli are destroyed in a one per cent. solution in thirty minutes, and Sternberg says, "In the proportion of one to two thousand, in an aqueous solution, SO_2 kills micrococci in two hours." The experiments of Baxter led him to the conclusion that "it is the most powerful volatile disinfectant known." Notwithstanding these high words of commendation I am inclined to the opinion that this gas can be too much relied upon as a disinfectant, and that the proper course lies in either supplementing its employment by other means, or in using it in a more concentrated form than has been the practice heretofore. For the disinfection of rooms recently vacated by diseased persons, five pounds of sulphur should be burned for each thousand cubic feet of air-space. The sulphur is best ignited by pouring over it three ounces of alcohol and applying a lighted match. Care should be taken to get the heat from the burning sulphur to generate a certain amount of vapor, since it is in this form that the gas exerts its powers as an antiseptic for decaying matters. To accomplish this the sulphur may be placed in a tin vessel and the latter then placed in another shallow vessel containing water, so that the heat will come in contact with the water. The apartments during the entire period of fumigation should be kept completely closed, and opened about twenty hours afterward and thoroughly ventilated. Before using this substance, however, it is necessary to have all carpets taken up, the wall-paper removed and burned, and all other hangings loosened up so that every part may become exposed and the gas reach every nook and corner. The chemical action of sulphur dioxide is supposed to be one of deoxidization and the resultant acid coagulation of albuminous substances. It is two and a quarter times as heavy as air, and has a peculiar pungent and disagreeable odor, which is perceived when a sulphur match is ignited. Sulphurous acid and sulphur dioxide are both destroyed by chlorine and permanganate of potassium, and should never be used in conjunction. The great solubility of sulphurous acid renders it one of the most valuable substances to sterilize liquids. Dr. Edson, of the New York Board of Health, says that sulphur dioxide is the most practicable and reliable means for the destruction of the contagia of exanthemata and diphtheria.

Another important and valuable antiseptic, though not a disinfectant, is found in carbolic acid. Its chief advantage is that it is a liquid and slightly volatile, and can, therefore, be sprinkled in apartments and upon substances, and thus penetrate every crevice and be of service. It requires about twenty-five parts of water for thorough solution, and in this proportion is a very powerful and thorough antiseptic. It coagulates albumin when of this strength, and enters readily into union with organic substances whenever brought into contact with them. Dr. Sansom has shown that a mixture of carbolic acid and glycerine is a delicate and effective application for diseases of the skin of a contagious nature. The chief property of this acid and of the compounds associated with it is the power of destroying vegetable and animal micro-organisms, and preventing the putrefactive and fermentative changes associated with their presence. Vaporizers for carbolic-acid fumes have been improvised by the means of hot metal plates upon which the acid is gradually dropped. Carbolic acid conceals all odors, though it will not destroy hydrogen sulphide, as is the case with chlorine, and it lessens the rapidity of putrefying matter suspended in the air; though it will not stop these changes entirely, it arrests the growth of fungi in fecal matter, and in stronger proportions will completely wither them. A mixture of one part of carbolic acid and nine parts of vinegar and a little gum camphor, is a simple and pleasant deodorant for apartments.

In addition to the foregoing measures of hygiene, sanatation, disinfection, and antisepsis as preventives of disease, there has arisen in recent years another distinct department of preventive methods as the result of investigations into the nature and mechanism of immunity or the refractory condition. This subject has been thoroughly discussed in another part of this volume, and needs no further treatment in this place. Whenever the alleged facts in regard to this doctrine of immunity shall have been thoroughly established, prophylaxis will, in making application of them as auxiliaries, have made a decided advance and have added to the fast-increasing amount of accessories. *J. Wellington Byers.*

PYOCTANIN (METHYL-VIOLET). Introduced in 1890, by Professor J. Stilling, as a powerful antiseptic for surgical purposes. He claimed that it possessed bacteriacidal properties equal to those of any other substance in use, and at the same time was perfectly harmless to the tissues. He had instituted a series of experiments, and found that 1 to 4,000 solutions prevented putrefaction up to the sixth day. Weaker solutions were found to prevent the growth of pathogenic bacteria. He experimented with a great number of the aniline dyes, and found that certain auramines proved to be the next best. These have been named yellow-pyoctanin. Upon animals he found that, when dropped into the eye, a 1 to 1,000 solution stains the conjunctiva, sclerotic, and iris, but not the cornea if uninjured. In the human eye it often causes a dilatation of the pupil without any paralysis of accommodation. When the surface of the eye is scratched, or if it is inflamed and injured, the part is immediately dyed, the degree depending upon the strength of the solution. The more recent the corneitis, the longer the stain lasts. If the action of the application is beneficial the coloration will be noticed to gradually fade; should it not do so, it is evident that there is no power of repair. When granulations exist they are readily and deeply stained. He never found any irritation to follow its use, even when the powder itself was dusted on the conjunctiva. The drug is perfectly harmless, Professor Stilling having injected large quantities subcutaneously and into the peritoneal cavity without producing any toxic action. He also filled large wounds with the powder without any unfavorable sign. After the injection of large quantities the abdominal organs and the tissues are stained, but the blood and the blood-vessels retain their normal appearance. Rabbits have also been made to eat the dye with their food.

In one of his papers, Dr. Stilling summarizes its qualities as follows: 1. Pyoctanin is an antiseptic surpassing all others. The bacteriological researches have shown blue pyoctanin to be about three times as strongly antiseptic against anthrax bacilli as sublimate is, and to be quite as efficacious as sublimate toward the staphylococcus aureus. 2. It is an absolutely non-toxic substance. 3. In consequence of this non-toxicity it is a matter of indifference in many cases of wounds, etc., whether somewhat weaker or stronger solutions, or even the pure drug, be used. 4. It does not coagulate albumin—a negative quality of high value physiologically, which pertains to no one of the antiseptics heretofore known. 5. It possesses an extremely high degree of diffusibility, permeates the interior of the eye like atropine, and acts similarly in other tissues.

Therapeutically, he obtained the greatest success in ophthalmic practice with a 1 to 1,000 solution, or by slightly dusting the part with a two per cent. powder. In conjunctivitis he considers that twenty-four hours will usually suffice to effect a cure. He also had good results with it in blepharitis, eczema of the lids, keratitis parenchymatosa, iritis serosa, choroiditis, and in one case of sympathetic ophthalmia. In blennorrœhal and gonorrhœal ophthalmia he obtained the best results by pencilling the parts several times a day until the membrane was quite blue. In granular lids a daily application of the pencil generally effected a cure more rapidly than when nitrate of silver or sulphate of copper was used. Pyoctanin was also used with success as a dressing in wounds, ulcers, and in acute suppuration. The following are the preparations advised for use: Pure methyl-violet, to be used as a powder for large wounds and ulcers. Large pencils, for small wounds, burns, etc.; for purulent cases the blue pencil is better than the yellow, on account of its greater antiseptic property. Small pencils, for ap-

plication to the eye in cases of corneal ulcer, etc. Powders, of one to one thousand strength for mild cases of conjunctivitis, for more severe cases a two per cent. powder is prepared; these can also be used as a snuff in affections of the nasal mucous membrane. Ointments, varying in strength from two per cent. to one part in ten; solutions, from one-tenth to one per cent.; the one to one thousand to be used for ordinary cases of conjunctivitis, keratitis, etc.; in non-purulent cases the yellow dye is used, on account of its greater cooling properties; the solutions should be filtered and kept in dark-glass bottles and changed every eight days. Gauze and medicated cotton dressings may also be obtained.

Since its introduction the drug has been very extensively used, with varying success. With some it has produced all the good effects that were expected of it, with others it has failed entirely, and in many instances has given rise to troublesome and painful irritation of the eyes. The unsightly stain it produces and the danger of destroying the linen, render it objectionable to many. The antiseptic properties of the drug have also been called into question. Liebreich considers that it is unsuitable for practice, as it is a mixture of different aniline compounds, and cannot have any definite character. Other investigators have failed to destroy the pus cocci with a 1 to 1,000 solution in twelve hours, and found that it was only with great difficulty diffusible in the tissues. Many of the failures are no doubt due to the inferior quality of the drug, and the irritation may often be produced by impurities present, but the very great difference of opinion that exists, and the numerous cases of successes and failures that are reported, envelop the subject in a great deal of uncertainty.

As an antiseptic it has been applied to a great variety of diseases, but has acquired a notoriety during the past year as a means of treating malignant disease. In January, 1891, Professor von Mosetig reported a number of cases treated by injections of pyoctanin, with very favorable results. For some time he had used the different forms of aniline as an injection, with the purpose of staining the nuclei of the cells and thus checking their growth, but the constitutional symptoms produced had always been a hindrance to the treatment. When Professor Stilling introduced methyl-violet he at once began to use it for this purpose. The germ-destroying power of the agent, in connection with its diffusibility in healthy and diseased tissues, made it a very promising agent, especially as it was also harmless and devoid of any injurious effect on the human economy. The first case was a woman, sixty-six years of age, with a large tumor of the lower jaw which prevented her from swallowing and caused great suffering. After thirty-five injections of six grammes of a 1 to 500, and afterward of a 1 to 300, solution, the tumor was so much reduced without ulceration that the patient could eat without discomfort. In the case of a man fifty-eight years of age, with a cystosarcoma of the chest-wall measuring thirteen centimetres in width by eighteen in length, after twelve injections of six grammes of a 1 to 300 solution, the measurements were reduced to ten by twelve centimetres. In two cases of adeno-carcinoma of the neck, the same treatment proved so effectual that the patients considered themselves cured. Another case was that of a woman, sixty years of age, with papilloma of the bladder; for which twenty grammes of a 1 to 1,000 solution was injected into the bladder every second day. After the injections there was notable improvement, the hæmaturia had ceased, and there was little or no pain. Professor Mosetig also cited a case of a man sixty years of age, with an enormous sarcoma of the pelvis; colotomy had been performed. After sixteen injections of six grammes of a 1 to 500 solution into different parts of the mass, it had shrunk to one-half its former size, and the patient was greatly relieved and able to walk about for a few hours daily.

Following Professor Mosetig's announcement came a number of cases treated by other surgeons with similar favorable results, and during the past year it has been employed very extensively both in Europe and on this side of the Atlantic. The results of the treatment have varied to an extreme degree, some surgeons claiming very remarkable cures, while others have failed to observe any signs of benefit, and look upon it as a perfectly useless procedure. The greater number of those who look with favor upon the treatment, including its author, do not claim that it is a curative agent for cancerous diseases, but simply that during its use the progress of the growth is checked, the local condition improved, and a temporary relief obtained. In a few cases a decided retrograde change has been observed, but permanent cures have not been very clearly demonstrated. The following directions are given for its employment: Under proper antiseptic precautions the part is to be carefully curetted until all the diseased tissue that is accessible is removed. When there is no ulceration of the surface, the curetting is omitted. After the curetting, a tampon of iodoform gauze is placed in the wound and allowed to remain for forty-eight hours. The surface is then washed and carefully dried and the injections made into the tissue, to the depth of the needle if necessary, according to the extent of the tissue involved. Other injections are made into the surrounding tissues, as many as fifteen punctures being made at one sitting. It is advised to begin with the deeper injections, in order to avoid a discoloration of the tissues on the surface in the early stages. After completing the injections, pure pyoctanin powder is introduced into the cavity, or, gauze or cotton, medicated, may be used. The tampon is left in position until the second day, when it is removed and the parts thoroughly washed and the injections repeated. The introduction of the solution exerts an analgesic action, and also checks the profuse hæmorrhage that is frequently present. When a favorable result is obtained the tissue is said to develop a more healthy granulating surface, the infiltration and tension subside, and the patient experiences relief from pain and discomfort.

Intra-pulmonary injections have been used for the treatment of pulmonary tuberculosis. The liquid employed was a 1 to 500 solution, of which eight to sixteen minims were injected. The injections are reported to have been well borne, but when the liquid penetrated to the bronchi, a violent attack of coughing was provoked. Therapeutically, it is said to have produced a lessening of the hectic condition and reduced the number of bacilli in the sputa. *Beaumont Small.*

PYRIDINE (C_5H_5N). A liquid body obtained from bone oil by treatment with sulphuric acid and subsequent fractional distillation to separate the anilines and other compounds. It may also be obtained by the dry distillation of bone, coal, etc., and as a decomposition product of various alkaloids. It is also present in tobacco smoke.

It is a colorless liquid, with a peculiar empyreumatic odor and pungent taste. It is very hygroscopic and mixes freely with water, alcohol, and oils. Its specific gravity at 32° F. is 0.9858. Pyridine resembles alkaloids in its property of forming salts with acids. It is distinguished from aniline bases by its power of resisting the action of oxidizing agents. Two drachms of a ten per cent. aqueous solution, to which three drops of volumetric permanganate solution have been added, should maintain the red color for at least one hour. Pure pyridine should not be altered by exposure to light.

Pyridine has been used as a cardiac stimulant in doses of three or four drops, three times a day. It increases the strength of the cardiac contractions, raises the blood-pressure, and diminishes the number of pulsations. It is recommended for use in the conditions in which digitalis is indicated, but must be used with caution, as its action is powerful, and vomiting, vertigo, and syncope have followed its use in individuals with much debility. It has proved of more service when inhaled for the relief of asthma, cardiac distress, angina pectoris, and in the dyspnœa of phthisis and laryngeal affections. Its action is prompt, and in many instances permanent relief is obtained. The ease that follows the inhalation of tobacco-smoke in asthma, is supposed to be due to the presence of pyridine. Germain Sée has studied its action in various forms of asthma and recommends it particularly when the disease

is of a nervous origin. One drachm is placed in a saucer in a closed room, at a temperature of 68° to 77° F. In about an hour evaporation will have taken place, and the patient should then inhale the impregnated atmosphere for fifteen or twenty minutes, which may be repeated two or three times a day. The drug may also be inhaled by placing ten or fifteen drops on a handkerchief.

It has been used as a local application in diphtheria, a ten per cent. solution being employed. An aqueous solution of one part to three hundred has also been recommended as an injection in gonorrhœa. The drug has not, however, established itself as a remedy of much value, and is rarely employed in this country. It must not be confounded with pyrodine, which is a preparation of hydracetine. *Beaumont Small.*

QUARANTINE. The term quarantine has lost its ancient significance in late years. Formerly held to apply to a period of time, it has now come to represent a method, rather than detention for a given number of days. The term is from the Italian *quarantana*, or forty days, that being the period which was established first by the Venetians several centuries ago.

The original quarantine establishment, although so long preceding the bacteriological period of medicine, was based on the principle of exclusion. To-day the same principle obtains, except that we now have a definite germ which we exclude. Formerly disease was supposed to be conveyed by the persons themselves, or in some unknown manner. The germ theory, which has now been accepted by scientific men the world over, rests, in brief, on certain well-known facts deduced from observation of the characteristics of epidemic and contagious diseases. It has long been known that cholera, yellow fever, and plague traversed the same route as commerce; that they went no faster than man could travel; that they spread precisely in those places where man went. This proved the germ to be a material thing, capable of being transported. It was further seen that after it effected a lodgment it spread in some manner, so that it was capable of self-multiplication. This proved the existence of a living organism. That it followed the rule of living organisms was further demonstrated by the fact that each of these diseases produced only after its kind; thus the seed or germ of *plague* being sowed in a place, *plague* only resulted, and no other disease as a direct consequence of that importation. It naturally followed, then, that the practical world was ready to accept the germ theory in its entirety as applied to contagious and infective diseases. It is on this theory that the modern quarantine system is based, that is, on the exclusion of germs. But modern quarantine goes further. Not only are the germs excluded, but they are *destroyed* by systematic application of germicides or anti-bacillary agents.

From the earliest times the practice of quarantine has prevailed as a personal right (*jus personæ*), and, by extension, as a national right (*jus gentium*). The right of a man to protect himself against the encroachments of an enemy naturally extends itself to that of protection of whole communities, political divisions, and countries, and is practically undisputed.

When we come to consider the details by which quarantine is carried out we find the greatest diversity of practice. *Regulations* of quarantine, even in those countries which are most lax in their practical administration, are extremely stringent, sometimes seeming to be in inverse ratio to their efficiency. Thus, in one of the South American Republics, three or four years ago, quarantine regulations which prevented passengers from any infected ship being landed on the shore were broken to allow a high officer with his suite to land from a ship having on board cholera patients, and on which several persons had died of cholera on the voyage. The rapid extension of the disease into the city and its environs, along the different lines of travel radiating from the port, soon followed, and the history of this epidemic remains to-day as a standing monument to the laxity of what seems on paper a very stringent and rigid quarantine. We come now to the practical details.

(*a*) By Sea.—When a ship arrives at a place designated on the chart as a quarantine anchorage of a certain port, she is boarded by the health officer or his authorized deputy; inquiries are made of the officers and the ship's surgeon, if there be one, as to the health of the crew, and the passengers if any; the nature of the cargo, from whence obtained; the length of the voyage, and the present sanitary condition of the vessel. These inquiries are made, not for the purpose of absolving the quarantine officer from making a careful inspection and satisfying himself as to the actual condition of the vessel, but for the purpose of placing the ship's officers on their honor in making their replies, and rendering them liable to the penalties of the law for making false statements. This safeguard is universal. After these inquiries have been made, the next duty of the quarantine officer is to call for the passenger list and crew list of the vessel. The health officer should have a sufficient number of enlisted men to be stationed at the gangway of the main deck of the ship; the passengers of the first and second cabins are then called upon the deck and formed in line. The officer takes his station at a convenient passageway, and the passengers, being called by name as they pass before him in review, are inspected and counted. If the count should fall short of the number on the passenger list assigned respectively to the first and second cabins, inquiries are made as to what has become of the missing passengers; or, if the ship's officers insist, a recount is then made. The reason for this is too obvious to require explanation. The passengers having thus been reviewed, the immigrants are next called on deck, and the enlisted men of the health officer again stand at the gangway to prevent passage or "doubling up" of the line on the reviewing officer. They are then formed in line and passed in front of the reviewing officer and counted. It must be apparent that the calling of names is an unnecessary performance, except that the exact number shall be accounted for, as borne on the passenger list.

This list should bear the visa of the United States Consul at the port of departure, in order to prevent the changing of the list or its manufacture en route, as it would be easy for the ship's officers, having lost a number of passengers, or a number of its crew, to substitute a new list for the one prepared before leaving the port of departure. Having made a careful inspection of the immigrants, the health officer next makes a tour of the ship. He should visit the state-rooms, closets, cubbies, and all such places on board the ship, and especially the quarters assigned to the steerage and immigrants, who should be required to remain on deck during this inspection. If any are ill the surgeon is interrogated as to the clinical history of the case; the patients are then examined by the health officers, and, in the event of there being contagious sickness, arrangements are at once made for their removal from the ship; and, in fact, the removal of all passengers should be immediately contemplated. This inspection need not require much time, and indeed up to this point the ship will have been detained only a short time. If, however, contagious disease be on board, the removal of all persons on the ship should be immediately made, the ship disinfected by approved methods, and allowed to join the commerce fleet at the earliest possible moment. The arbitrary detention of the ship for a given number of days is contrary to modern principles of sanitation. The well persons on board the ship should be removed to comfortable quarters on shore, and detained only long enough to fully complete the period of incubation from the time of leaving the port of departure, or of immediate personal contact with the sick. Thus, for instance, a ship leaving a port of Europe infected with cholera and arriving in this country ten days thereafter, may be reasonably presumed to have passed the incubation period, and the passengers of said ship should be set free without other detention than is required to ascertain if they are at the time healthy.

New merchandise, and the clothing actually worn on the bodies of such persons, need not be detained for disinfection, but all soiled linen and baggage packed in an infected port should be subjected to proper disinfection

before being delivered to the passenger or his agent. The same rules may be applied to immigrants, with this exception, that the immigrants themselves, being usually in cramped and crowded quarters, are more likely to have their personal clothing infected by contact with the sick than are the cabin passengers, who have more freedom and more exposure to air-currents.

No general rule can be well laid down for the treatment of cargoes of vessels without taking a general list of all goods and merchandise composing the cargo. Some cargoes are extremely liable to convey infection, while with others it is almost impossible, and there is no circumstance which can bring out in more bold relief the wisdom or folly of the inspecting officer than the orders given in regard to the disposition of the cargoes and different articles of merchandise. New goods packed in a manufactory and baled, shipped by ordinary channels of trades, are little likely to convey infection in any case; nor does the writer know of a single instance where an epidemic has been traced to the importation of new merchandise. Personal baggage and effects, soiled clothing, old rags, and the like are, however, subject to very different conditions. Persian rugs and articles of that kind, which investigation shows may be many years old, and in some cases handed down as family heirlooms, and finally sold to the trade—it may be after the death of the family by plague or cholera,—require disinfection by steaming; and soiled rags should either be steamed or delivered to the rag manufacturer on his giving bond that the bales will be opened at the paper mill or elsewhere, and dumped in a vat containing disinfecting solution, before being exposed to sorting by the operators.

The establishment of the quarantine comprises suitable barracks for the detention of the well; disinfecting chambers for the steaming of certain classes of baggage, and provision for the aëration of others liable to be damaged by steam or sulphur fumigation. Latrines constructed on scientific principles, and hospitals for those sick or injured, and an isolation hospital, or a series of isolation tents, for those affected by contagious diseases, and warehouses for the proper handling of baggage; an abundant supply of pure water; proper arrangements for lighting, heating apparatus, suitable quarters for commandant, mess-rooms, kitchen, lavatory, and laundry, and, at large quarantines, provisions for electric lighting;—all these should be provided. In addition, there should be separate quarters for the guard, and outside of these a wharf where supplies can be received, immigrants received and discharged, and communication be had with the marine patrol. The details of the force for the administration of the quarantine need not be detailed here, but they comprise briefly: Proper crews for sanitary service; waiters, male and female; nurses, male and female, for the sick; sufficient force for the supply of food; medical officers, and such others as the importance of the quarantine and the number of persons to be passed through seem to require. The marine patrol is necessary for the guarding of the ships detained in quarantine refuge undergoing disinfection, for the arrest of any persons attempting to board a ship without due authority, for the prevention of any communication between the ships and the quarantine on the one hand, or the shore on the other. This patrol must be more or less extensive, according to the area of the quarantine anchorage and its distance from the shore. If it be very near the shore, the patrol must be maintained with great vigilance to prevent communication. A quarantine in which the ships are not kept properly guarded, will be futile.

It has before been stated that the ship should be restored to the commerce fleet as early as possible; to accomplish this it is necessary that the disinfection of the ship be begun as soon as the passengers shall have been discharged from it, and maintained without intermission until the inspecting officer pronounces the ship fairly clean and no longer liable to convey infection if allowed to go to her dock in the city. It is obvious, in this connection, that there must necessarily be a variation in the regulations governing different ports; at ports where the ships are discharged in lighters, and where they do not require to enter the dock, the liability to convey infection is extremely limited, and the regulations may be conducted with less stringency than at ports where the vessel goes directly to her dock. However, there must be constantly borne in mind the maxim of marine hygiene, that the highest rule should be "a clean ship sailing from a clean port."

In some quarters it has been stated, and is sought to be constantly kept before the public, that quarantine is antagonistic to hygienic measures, and that reliance upon quarantine necessarily breeds indifference as to municipal hygiene and municipal sanitation; in fact, the contrary is the case, for modern quarantine is but the practical application of hygienic law.

(*b*) By Land.—Land quarantines, while operated on the same principle, are extremely difficult of management, requiring not only faithfulness and honesty on the part of the inspector, but patriotism as well. The inspector should be indoctrinated with the necessity resting upon him for vigilance far greater than that which rests upon the marine inspector, because the dangers of communication are greatly increased.

The inspection of railway trains and vehicles is confined to an examination of passengers on the train. They should be required to pass out at one end of each car, commencing at the baggage car; the inspector should require every person on the car to pass out of the rear end of the car, he having at the time an assistant on the platform while he takes his station on the ground where the passengers disembark. Each passenger then passes in review before him, and, when the car is empty, may re-enter at the other end. Persons who are feeble from disease or otherwise may be passed to one side and placed under guard, while the remainder of the passengers are reviewed by the inspector. He then turns his attention to the passengers who are detained, and examines them with a view of determining the nature of their illness; and if they are found with contagious disease, they are detained and placed in an isolation hospital provided for the purpose. It is usual in America, in a place in which an epidemic has been delared to exist, to furnish out-going passengers with certificates that their baggage has been disinfected under proper inspection. A failure to have such certificates should require that the baggage be detained and passed through the process of steaming, or other disinfection, at the discretion of the health officer. Sleeping-cars should be prohibited from entering an infected city or place; but as a matter of detail, it has been permitted repeatedly, in times of epidemic, for through passenger trains to pass directly through such places without stopping, which, in such cases, prevents their being infected, as infection is not carried by the air-currents. It is only when the air becomes stagnant and thoroughly infected by being confined, that it becomes dangerous.

The much abused *cordon sanitaire* is a line of guards extending across a given country for the purpose of preventing overland travel, except after authorized inspection. It is certain to fail in cases where the guards are unfaithful or where they are liable to be bribed. It has for this reason fallen into great discredit in some countries. In the United States, however, an instance of bribery has never yet been demonstrated, and the *cordon sanitaire*, as maintained in Texas and Florida, and in other places by the government, three of them under the writer's own direction, have been entirely successful in preventing the spread of the disease beyond the established line.

The Quarantine Laws of the United States.—The quarantine laws of the United States are of two kinds, State and National. State laws vary in many particulars, those of the seaboard States being entirely different from those in the interior; but the National laws follow a uniform and definite course. The first quarantine act was passed February 1, 1799, and is embodied in the present revision of the Revised Statutes, Section 4792.

Its general provisions are, that all officers of the

United States shall lay State and local quarantines wherever practicable, and in such manner as they shall be directed by the President of the United States, or the officers over them. Further, in regard to the regulation of vessels entering ports, the collector of customs of such port is directed to withhold entry until such time as a permit of the health officer shall first have been obtained.

Provision is made for the erection of suitable warehouses for the storing of goods from infected ports; and also for the unloading of cargoes of vessels. And, it further provides for the removal of certain public officers and the courts in the event of an epidemic breaking out in a given place. This law was passed under the stress of the great epidemic of yellow fever which had previously prevailed in Philadelphia and New York; and it may be said, in passing, that nearly every law on the United States Statute books bears a relation to some previous epidemic.

The next law, and that most relied on at present, is the law of April 29, 1878, framed by Surgeon-General John M. Woodworth, which prohibits the introduction of any vessel or vehicle from any infected ports; passengers, goods, and merchandise from infected ports; and places the execution of the act on the supervising Surgeon-General of the Marine Hospital service, subject to the approval of the President of the United States. It was for the first time provided in this act that representatives of the United States in foreign countries should give immediate notification of the existence of any contagious disease in any of said countries, in order that proper information might be had in this country. The act of 1878, however, did not provide any penalty which could be enforced against persons violating any of its provisions; consequently, in the act establishing eight quarantine stations, framed by the writer, approved August 1, 1888, a proper penalty for persons violating the quarantine was provided, and eight quarantine stations to be operated by the United States were established by the said act, viz., Delaware Breakwater, Cape Charles, Sapelo Sound, Tortugas Keys, San Francisco, Cal., San Diego, Cal., Port Townsend, Wash., and Chandeleur Island.

The powers of the Government over quarantine matters were further promulgated by the Inter-State Quarantine Act of March 28, 1890, also framed by the writer, whereby, whenever the President becomes satisfied of the existence of contagious disease in any State, and that there is danger of its spreading to another State, he may cause the supervising Surgeon-General of the Marine Hospital service to frame such regulations, subject to the approval of the Secretary of the Treasury and the President, as in his judgment are necessary to prevent the spread of the disease from one State to another. With the passage of this law it was believed that the powers of the Government were fully expressed on the Statute books, and that all necessary action could at any time be taken. As the Constitution of the United States gives Congress the exclusive right of legislation in all matters relating to commerce, commerce can thus be stripped of its power to convey contagious diseases by suitable regulations, and in the exercise of these laws there was no invasion of the rights of the State, but simply the exercise of a power wholly within the jurisdiction of the Government. A construction, however, was placed upon the act of 1890, which rendered it nugatory and of little effect. And in February, 1893, Congress enacted a law embodying the substance of former laws, and imposing new duties on the Marine Hospital Service, whereby complete surveillance is maintained over ships carrying immigrants from foreign ports. Under this act medical officers of the United States are detailed whenever there is need, to serve in foreign ports of departure and certify the condition of ships bound for ports in the United States. *John B. Hamilton.*

RABIES. Since the appearance of this work there has been uninterrupted effort, upon the part of many able investigators, to satisfactorily prove the position which inoculation with the modified virus of rabies is to occupy in the treatment of this most frightful disease.

The opinion which was held at the time of issue of the former article was cautiously expressed as follows: ". . . There are strong reasons for the hope that it [preventive inoculation] may prove to be a safe and sure preventive of the rabic disease."

The laboratories then in use for this purpose have furnished additional knowledge concerning the efficacy of inoculation against the bites of rabic wolves and other savage animals, the result of actual experimental research under the most trying and persistent conditions of absolute control. These labors have been made public in the Bulletins of the Pasteur Institute, and have been of so convincing a character that additional institutes have been erected in various countries for the treatment of patients with rabies in the manner laid down by the illustrious originator of protective inoculation; and this treatment is to-day regarded as the only successful method of preventing the appearance of that dread malady. Such an institute has been in constant operation for some years in the city of New York, from which also reports and bulletins are issued from time to time. The last of these to reach the profession is contained in the *New York Therapeutic Review* for January, 1893, in which a record of eighty-three cases is published.*

The patients in the New York Pasteur Institute are divided into classes as proposed by Pasteur, consisting:

1st. Of those patients who had been bitten by an animal in whom the existence of rabies was clearly proved by experimentation (injection beneath the dura mater of a fluid containing minute portions of the suspected animal's nervous system), and by the typical course of the disease to its fatal termination in the inoculated animal.

2d. Those who had been bitten by animals recognized by competent clinical authority to be suffering from genuine rabies; and

General total					83				

The column A refers to persons bitten by animals in which hydrophobia has been evidenced by experimentation or by the death of some other persons or animals bitten by them; column B to persons who have been wounded by animals having been recognized mad by the clinical or veterinary examination, and column C to cases in which hydrophobia could only be suspected, as the animals had disappeared or were killed instantly and their bodies thrown away.

These eighty-three persons treated, came from—

2 Alabama.	1 Mississippi.	1 Pennsylvania.
11 Connecticut.	2 Missouri.	1 South Carolina.
2 Iowa.	30 New Jersey.	3 Tennessee.
4 Maryland.	4 New York.	2 Texas.
3 Massachusetts.	1 North Carolina.	14 Virginia.
1 Michigan.	1 Ohio.	

No death has been reported from among these persons.

3d. Those in whom the existence of the disease could only be suspected, owing to the fact that the animal from which the bite was received had either disappeared or had been immediately killed, and the carcass destroyed or rendered unfit for study.

Of the patients mentioned in the table (which accompanies the report and which we have reproduced on the preceding page), eighty-three in number, it is rather interesting to note that fifty-five, or the large majority of the entire number, were residents of three States, viz., New Jersey (30), Virginia (14), and Connecticut (11), while the rest of the patients, twenty-eight in number, were residents of fourteen States. These include a wide range of territory, comprising Alabama, Ohio, Michigan, Texas, South Carolina, etc., so that the effects of locality or surroundings may be justly disregarded. The report covers a period of nine months, from March 1 to November 30, 1892, and concludes with the statement: "No death has been reported from among these persons."

From this report it would seem that the preventive treatment of rabies by inoculation of the attenuated virus, according to the method of M. Pasteur, may be considered thoroughly successful, and that it constitutes at present the only rational and safe mode of treatment which has thus far been discovered. This boon is now being made available to sufferers from rabies in almost all parts of the civilized world, by the establishment of institutes similar to that of M. Pasteur in Paris.

Albert N. Blodgett.

RAMSGATE. One of the most popular of the English seaside resorts. The place is prettily situated on the Kentish coast, the cliffs and remarkably fine sandy beach being its special features. The climate is decidedly bracing, although the town itself is said to be warmer than Margate. The sanitary condition of Ramsgate is good, the death-rate being about nineteen per thousand.

According to Black ("Watering Places in the British Isles"): "Few places can boast such perfect bathing accommodation, both in the open air and at the baths, which are elegantly fitted up with luxurious seats in the reading, waiting, and refreshment rooms. There are machines under the east cliff, and baths there in front of the harbor and at west cliff—these last being the best. The sands are pre-eminently good, though there is little privacy. Otherwise they are excellent, and stretch right away to Broadstairs. Dumpton Bay, midway on the road thither, about three-quarters of a mile from Ramsgate, would be an especially beautiful and retired spot, were it not for the proximity of the favorite foot-path to Broadstairs, on which account ladies have frequently to turn back here, owing to the recklessness of bathers."

The Ramsgate season extends from June to October, and during its height the resort is often uncomfortably crowded. Tally-ho coaches run to Canterbury during the summer months, and there are many facilities for interesting excursions. The place is a favorite one for Londoners, though it is not particularly exclusive.

Edmund C. Wendt.

RECTUM, ULCERATION AND STRICTURE OF. In reading again what was written on this subject a few years ago, when this work first appeared, the necessity for revision and addition becomes very apparent. It has appeared to the writer that our present knowledge may perhaps best be stated in the form of several separate and distinct propositions.

I. *In all cases of non-malignant ulceration and stricture, the symptoms due to the ulceration must be distinguished from those due to contraction, in order intelligently to select the proper treatment.*

Although ulceration is usually the cause of non-malignant stricture, and is generally associated with it, there may be much ulceration and very little contraction, or there may be great stenosis with a comparatively small area of ulceration. In the one case the patient will suffer chiefly from the muco-purulent discharge, pain, and tenesmus; spending days and nights upon the water-closet, and losing flesh and strength from exhaustion, pain, and loss of sleep. In the other case, the muco-purulent discharge may be trifling and the calls to stool but little more frequent than natural, while the patient is in imminent danger of death from chronic or subacute intestinal obstruction. It is manifest that in the former case the mere enlargement of the canal would do little to relieve the patient's sufferings; while in the latter the relief of the contraction would restore the sufferer to comparative health.

Take, for example, a case recently sent me by Dr. Richardson, of New York. The patient was a young married negress, who during her whole life had never had a passage of fæces larger in diameter than her little finger, and for some months had scarce been able, with laxatives and straining, to have any at all. There had never been any blood, pus, or mucus in the stools. Examination showed a tight, falciform, congenital narrowing of the rectum at the usual site of this deformity, about two and a half inches from the anus, with little or no ulceration above it. The whole large bowel was loaded with fecal matter. The treatment in such a case is plain, and the woman was cured, or perhaps it would be more correct to say relieved and rendered perfectly comfortable, by dividing the stricture and subsequently using bougies, a treatment which, it is manifest, would have been of little use had there been any great amount of ulceration above the contraction. This brings us directly to the second proposition.

II. *Proctotomy and dilatation by bougies have a very limited range of utility, being applicable only to cases of non-malignant stricture, where the obstruction is of greater importance than the ulceration.*

Here let me say that proctotomy and the use of bougies are never indicated in cancerous stricture. Cancer of the rectum is not a thing either to be cut into or to be stretched open. Either remove it, do colotomy, or let it alone. Either course may be good surgery, but incising it, stretching it, or cauterizing it is meddlesome surgery, and attended by the same result as meddlesome midwifery. Under the head of cauterizing may be included electrolysis, which to accomplish anything must be either destructive cauterization, or gradual and simply mechanical dilatation.

If we limit thus the operation of proctotomy to non-malignant strictures, there are many cases where great benefit may be derived from it. I have even effected by it, in conjunction with subsequent dilatation, what may fairly be considered a radical cure; but unfortunately such results are few and far between, and are confined to cases of limited disease without much attendant ulceration and destruction of mucous membrane. In more severe cases of old stricture and ulceration, where the amount of disease rendered extirpation out of the question, and the treatment evidently lay between proctotomy with dilatation and colotomy, I have also in a few cases rendered the patient more comfortable by the former means than he would have been by the latter. But these cases have not been frequent enough to prevent my advocating as the safer course colotomy. Proctotomy may do good, colotomy certainly will. The former, in such disease as is here referred to, is a dangerous operation — much more dangerous than colotomy. In neither case will the patient have any control over his evacuations, though in one they will take place from the groin and in the other from the anus. One must be followed by the use of bougies as long as life lasts, the other needs no after-treatment.

The patient's condition in life is an element in choosing the treatment. Proctotomy and dilatation in hospital and dispensary practice are failures. The patients submit to an operation and expect to be cured, not realizing that proctotomy is but the first step in the treatment, which is really that by perpetual subsequent dilatation. This they have neither the time nor the patience to go on with. Better in these cases to do a colotomy at once than to add one more to the incisions already made. The best result I ever obtained from division and subsequent dila-

tation was in an old stricture of thirty years' duration, reaching above the limit of digital examination. The patient was a wealthy man, and willing to give any amount of time to the pursuit of health. The division of the stricture nearly cost him his life, but, recovering from that, he began the intelligent use of bougies upon himself, and at the end of a year used the largest instruments with ease, had one daily evacuation, and was only troubled by an involuntary escape of muco-purulent matter from the anus. Such a result is a manifest impossibility in a laboring man in hospital practice.

III. *In the severe forms of non-malignant ulceration and stricture, which are incurable by local applications, the proper treatment is either extirpation or colotomy.*

Here we must consider ulceration and stricture separately, as well as combined. Ulceration, either with or without stricture, may call for colotomy or extirpation, and stricture, with little ulceration or much, may do the same.

Colotomy for non-malignant ulceration, irrespective of stricture, we owe to Bryant, and it is one of the great advances in modern surgery. Following the general tendency of the day, I have also practised and advocated resection in a certain class of cases of non-malignant ulceration, exactly as would be done for malignant disease.

The rule of practice may be plainly stated. There are many cases of non-malignant ulceration of the rectum which are incurable, either by local applications or by constitutional treatment, and which in the end destroy life by exhaustion, loss of sleep, pain, and tenesmus. When the ulceration is limited in extent and can be reached by any incision, either dorsal or perineal, the ulcerated bowel should be excised, and the healthy gut above the disease sutured in the healthy gut below. If the disease be too extensive for such an operation, or if its exact limits cannot be determined beforehand, a colotomy should be performed.

Exactly the same rule may safely be followed in cases of non-malignant stricture. If the disease cannot well be kept in abeyance by incision and subsequent dilatation, it should either be excised or a colotomy should be done; and which, must depend upon the extent of the disease and the surgeon's individual practice and preferences.

It follows from this that a surgeon may do a colotomy in a case of combined ulceration and stricture for the ulceration alone, where the stricture could easily be overcome by dilatation. Mere stenosis is much easier to overcome by local treatment than is ulceration.

Given a case of extensive non-malignant stricture, say venereal or dysenteric, where the whole area of the disease covers only two or three inches of the bowel, the surgeon will be governed in his choice between extirpation with circular suture and colotomy by his individual preferences, always bearing in mind, however, that colotomy is an operation with almost no mortality, and that the same cannot be said of extirpation in any of its forms.

IV. *In non-malignant disease either extirpation or colotomy may restore the patient to perfect health and usefulness.*

In this article so far, I have spoken of colotomy as an accepted surgical measure of which the utility was fully recognized. I shall do so to the end. To anyone who denies the propriety of colotomy in certain cases, the whole article will be unintelligible and unacceptable. It is with me always a last resort, exactly like the amputation of a limb. To cut off a leg is to acknowledge the inability to cure the leg. To cut off the rectum from the function of defecation is to acknowledge the inability to cure the rectum. But to amputate a leg is still good surgery, often the best and only surgery, and to cut off the rectum from the rest of the alimentary canal is often the same. In disease of the knee-joint the surgeon may sometimes resect and sometimes amputate. In stricture and ulceration of the rectum we may do the same. It is often a question whether a leg after resection of the knee-joint is any better than a good healthy stump in the thigh, and it is often a question whether a rectum which has been operated upon by excision is any better than an artificial anus in the groin. It is long since anybody has contended that a man who had lost a leg by amputation had better be dead, and yet the time has not come when we do not hear that a man who has lost his rectum and whose descending colon ends in the left groin, is not better dead than alive. With those who hold such views this article can have no weight.

They tell me that over on Blackwell's Island there are a number of paupers who have submitted to lumbar colotomy, whose condition is very pitiable. To this I can only answer that I never do lumbar colotomy, and that none of the many patients upon whom I have done the inguinal operation is at all anxious to die. My cases are all about me, and I keep in communication with them as long as I can. Are any of them perfectly happy? Are they as well off as they would be if they never had had incurable disease of the rectum? No. But are they better off than they were when operated upon; and has a condition tending toward the grave been changed into one of comparatively slight discomfort? Yes. No patient of mine has ever reproached me for doing a colotomy upon him, though I have had a patient complain bitterly to me that, in spite of the operation, there was still a little muco-purulent discharge from the anus, and that there was a slight erosion of the mucous membrane at the artificial opening. In the same letter he has told me that he had gone back to his daily labor as a house carpenter after years of invalidism, and had gained forty pounds in flesh.

I have no desire to make the state of a patient with an artificial anus appear more comfortable than it is, and I have no prejudice in favor of colotomy over any other method of treatment that will prolong life and relieve suffering. I had as lief extirpate the rectum as to do colotomy, and could I do any good, I had as lief paint it with nitrate of silver as do either. I can only say that upon this one point there is a popular prejudice which is to be overcome by practical experience, and which will be overcome by any considerable experience with the results of colotomy. I should probably be as slow as anyone to recommend a surgical operation which I thought was to cover me with reproach, and I do not do colotomy with the idea that my patients will in the future execrate me. It is advised, advocated, and recommended as a thing which will improve the condition of, and be satisfactory to, the patient, and in all my cases the result has justified the recommendation.

In choosing between extirpation and colotomy in any particular case, it must also be remembered that the difference in the condition of the patient after the two operations is not as great as at first sight it might seem. Extirpation often leaves a useless rectum and anus after great risk and long convalescence; and there is not much to choose between an artificial anus with no sphincteric power in the perineal or sacral region, such as often results from extirpation, and the same condition in the left groin after inguinal colotomy. For the latter we never claim any sphincteric control, while for the former it is often claimed with only the slightest foundation. It is indeed quite the rule to see in the reports of cases of extirpation, that the patient has good sphincteric control, though sometimes the words "except in case of diarrhœa" are added as a saving clause; and yet as I write I am trying to remember a single case of real sphincteric power after extirpation of the lower part of the rectum, either in my own practice or in that of others, which has come under my observation. It must be very rare. We all know how common is the disabling of these slender muscular bands after operations for not very extensive fistulæ, and how commonly we see incontinence associated with even slight stricture and ulceration within the rectal pouch. What then is to be expected after such extensive cutting and cicatrization as is involved in the operation of extirpation?

A study of the physiological anatomy of the function of defecation, leads one to smile when he reads in a journal that a patient has "sphincteric control except in case of diarrhœa." It is much like saying that a man has good use of his legs except when he tries to

walk. And yet what is meant is this:—After complete removal of the sphincters and several inches of the rectum, a patient will often have sufficient warning of the approaching act of defecation, when the passages are solid and normal, to allow him time to prepare himself for it by seeking the closet, a warning of from a couple of minutes to half an hour. The warning is simply the normal involuntary peristalsis of the large bowel forcing its contents toward the anus, which is felt in every man as the premonition of an approaching evacuation. The difference between a man with perfect sphincters and one without, is that the former can *prevent* a passage even when the rectum strongly demands relief, and even in case of diarrhœa. I don't know that I have ever seen a case of extirpation of even a small part of the sphincters where this power remained.

It is the same with the colotomy patients. They have the premonition and have time to prepare themselves, but of actual sphincteric power, there is none. The advantages of an outlet to the alimentary canal without sphincteric power in the perineal or sacral region, over one in the groin, may not be great enough to compensate for the risks of an extirpation over that of colotomy; and yet I would not be understood as advocating either operation in preference to the other. Where the disease, be it stricture or ulceration, can be extirpated without too great risks, and too great destruction of the parts—in other words, where it is comparatively limited in extent and freely movable on surrounding tissues—extirpation is to be chosen. Where the extent of the ulceration is not positively known, or the removal of the stricture involves a more or less extensive removal of the pelvic contents, colotomy is preferable. Both operations will invariably give great relief and may restore the patient to perfect health. In the more extensive cases, even after colotomy, there may still be some discharge of bloody mucus and pus for a considerable time in steadily decreasing amount; but this, though always a cause of annoyance, will in no way prevent the general good result.

V. *In cancer of the rectum there are but two methods of treatment to be recommended, extirpation and colotomy, all other operative procedures being worse than useless.*

This has already been referred to under the second proposition. Proctotomy in cancer is a dangerous procedure, both on account of shock and secondary hæmorrhage, and can do but little good. It may temporarily overcome obstruction, but for a very limited time and at great risk. The same applies to cauterization with acids or actual cautery, to partial extirpation, *râclage*, and electrolysis, the means usually adopted by those who assume to treat these cases, and yet refrain from radical surgical measures. For the man who will not extirpate and who believes colotomy to be worse than death, there is nothing else to do, it is true, but it is better to do nothing than to do harm, and such a man had better leave these cases to others. This brings us to the next proposition, that:

VI. *In the vast majority of cases of cancer, either extirpation or colotomy should be done as soon as the diagnosis is certain.*

I have seen in the aggregate many years of useful life lost by the advice of reputable surgeons, who, recognizing the disease, and the necessity for future colotomy as a means of preventing obstruction, have not recognized the utility of immediate operation for avoiding pain, loss of sleep, and exhaustion. Cancer kills in several ways, but least often, I think, by causing obstruction. Generally it is by exhaustion; and the chief elements are the rapid decline in strength and the almost constant desire for stool, with its attendant bleeding, straining, irritation of the growth, and loss of sleep. There is, moreover, but little doubt in my mind, though this is hard to prove, that the constant straining at stool caused by the growth, reacts unfavorably on the growth itself, causing its more rapid increase.

For these reasons I have made it a rule to do colotomy in nearly every case as soon as it is evident that a cancer exists which cannot safely be extirpated. The exceptions are the few cases in which, though extirpation may be contraindicated on account of the extent or location of the disease, there is still little irritation from the growth and no danger of obstruction. Such cases are occasionally seen, though not often. I have one in mind now, a young, apparently healthy woman with cancer of the upper part of the rectum involving also the peritoneum and uterus, and to my mind, therefore, not operable, in whom there were no symptoms except a discharge from the anus two or three times in twenty-four hours. In such a case it is as well to wait till either there is more local distress or some signs of obstruction, but one or the other of these equally pressing indications for operation is sure to come within a very few weeks.

It is in this sense that Bryant complains so justly that the operation of colotomy is too much regarded as a *dernier ressort*. We put it off until only a few weeks of life remain, when by doing it earlier life might be prolonged many months; and this, I suppose, will continue to be the general practice until the old idea, that the operation inflicts a disgusting deformity, is eradicated from the minds of the general profession.

VII. *The field of usefulness of the operation of excision of cancer of the rectum is very limited.*

It costs me much to write this proposition, for I have had great hope, some experience, and many failures. I know that in the attempt to cure I have more than once shortened life, and yet I have always been conservative. Let me for a moment glance at my own statistics. In one hundred and seventy-five cases of stricture, eighty-five have been malignant, or roughly speaking, one-half. In how many of these I have recommended colotomy, and in how many extirpation, I do not know, nor is it important; but in forty I have done the former, and in eighteen the latter operation. I am speaking now of cancer to the exclusion of non-malignant stricture and ulceration. The result of my extirpations is as follows, taking them in their order.

Case I.—Excision of cancerous mass on anterior wall of rectum three inches from anus, involving peritoneum. Death in fifty-two hours from exhaustion.

Case II.—Circumscribed growth confined to rectal wall at level of prostate, and covering a diameter of about two inches. Recovery from operation, but no history after the first two months.

Case III.—Cancerous stricture just within rectum, involving only about two inches of the gut, freely movable except as it involved recto-vaginal septum, and eminently suitable for extirpation.

The whole diseased part, with half an inch of healthy gut above and below, together with the recto-vaginal septum near the growth, was removed. Note the result. The disease returned almost immediately in the cicatrix, and a second operation, also completely successful, was done six months after the first. Again there was almost immediate return in the cicatrix, and one year after the first operation colotomy was performed.

Case IV.—Stricture with complete obstruction. The disease was confined to the middle and lower portions of the rectum, and was fairly suitable for extirpation. A complete circular resection was done, but the patient died in twelve hours from extravasation of fæces into the peritoneum. In this case the bowel above the cancer was much thinned by the long-standing obstruction, and the sutures tore out as they would from wet paper.

Case V.—Another perfectly suitable case for operation. The disease involved only the anus and recto-vaginal septum, and was completely removed. It returned in the cicatrix in three months, so extensively that no secondary operation could be done, and a colotomy was performed prolonging life one year.

Case VI.—In this the disease was more extensive than I should again attempt to extirpate. It was attached to the base of the bladder and involved a good deal of the peri-rectal cellular tissues. To give the patient every chance a preliminary colotomy was done a fortnight before the excision. Death followed the operation of extirpation in twelve hours, from shock.

Case VII.—Epithelioma of margin of anus. No return of the disease after two years as far as known.

Case VIII.—Circumscribed cancerous ulcer on side of

bowel about three inches long by two wide. Two-thirds of circumference of rectum removed for lower three inches. No return for three years.

Case IX.—Cancer attached at deep urethra and prostate, but movable at all other points. Extirpation of lower three inches of rectum. Return of disease in the wound before cicatrization, and death from secondary disease in liver a few months later.

Case X.—Cancer involving anus, base of bladder, and prostate. Amputation of lower three inches of rectum with removal of seminal vesicles and part of prostate. Death from exhaustion on tenth day.

Case XI.—Cancer of margin of anus, lower part of rectum, and recto-vaginal septum. Amputation of about three inches of rectum. Return in both groins in six months. Second operation, followed by return in three months.

It is unnecessary to report more cases in detail.

In four cases death was directly due to the operation. The chapter of accidents has been large in these cases, it is true, one dying from an injection of persulphate of iron into the peritoneal cavity by an attendant who became terrified by a slight oozing from the rectum during my absence; and one being exhausted by hiccough on the ninth day. But though bad luck and accidents will make the rate of mortality larger, it will of necessity always be large in this operation. For extirpation of the rectum is a serious and difficult operation, necessarily attended by great shock and loss of blood, and the possible complications are many and serious.

In two cases the disease, though thoroughly removed, returned soon in the cicatrix and the operation did no good. Both of these were typical cases for the operation, the mass being easily reached and freely movable.

In one case it is impossible to tell how much good was done by the first and second operations. Possibly life was prolonged over what it would have been by a colotomy performed as soon as the disease was recognized, perhaps not. At all events two serious operations on the disease itself only postponed the colotomy one year.

Our good results are reduced, therefore, in the cases quoted, to three cases of epithelioma of the margin of the anus and rectum, and to possibly one in which the result is unknown.

It seems to me that in such a question as this we should consider not so much the fact that by an operation attended necessarily by a high death-rate we can remove a cancer of the rectum, but the length of life which is likely to be gained as compared with other methods of treatment. In the fatal cases we sacrifice much life which might have been greatly prolonged by colotomy. In cases of immediate recurrence in the wound we certainly do not gain enough to pay for the risk. In those in which recurrence takes place only after an interval of months we may be fairly said to have accomplished good.

As to the prospect of cure in any but exceptional cases, such as epithelioma of the margin of the anus and rectum, it is rather a matter of hope than of probability.

In this operation of excision history bids fair to repeat itself. It was established as a legitimate mode of treatment by Lisfranc in 1830, and was subsequently almost abandoned on account of its use in improper cases and the necessarily bad results. Again, within the last twenty years it has become very popular, and once more it may be best to consider very carefully its results, particularly in the light of what can be accomplished without risk by colotomy in the same class of cases. Years ago Van Buren laid down a very simple rule as to the class of cases in which excision might reasonably be expected to do good. They were the cases in which the growth was movable on the subjacent tissues, distinctly circumscribed, and within reach from the perineum. Since the high sacral incision has come into use the distance of the growth from the anus and consequent opening of the perineum are no longer in themselves contra-indications to operation; but the limited extent of the disease and its movability are still the two things on which the decision to extirpate should turn.

To refer once more to my own experience, I may say that I am done trying to dissect a cancerous rectum away from the deep urethra with knife and dissecting forceps, as I am also done removing the deep urethra, prostate, seminal vesicles, and base of the bladder for the sake of getting out a cancer of the rectum. Epithelioma of the anus and adjacent rectum should of course be removed where we can cut wide of the disease, as we do in epithelioma of the lip; and these cases give us our real successes. Annular carcinoma in any part of the rectum, high or low, which is freely movable, may also be excised, but the chances are enormously in favor of a return within a few months, even in the cases most favorable for operation. There is no escape from the conclusion that cancer of any part of the alimentary canal holds out little hope of radical cure by removal, and is very likely to return after a comparatively short interval, no matter how thoroughly it may be extirpated. The technique of the operation has been greatly improved, and many cases have been brought within the field of justifiable operation, which a few years ago were considered inoperable. It is indeed wonderful how much can now be removed without fatal result; but the length of days gained by the patient bears small relation to the brilliancy of the surgery.

Our last proposition is this:

VIII. *The utility and advisability of inguinal colotomy in cancer of the rectum are unquestionable and the results most gratifying.*

In any case suitable for extirpation—that is, in any case where the disease is confined to the alimentary tube and does not in addition involve more or less of the pelvic contents—the surgeon may choose between extirpation, with all its risks, and colotomy. He may indeed first extirpate merely with the hope of gaining time before recurrence, and be prepared subsequently to do colotomy, as I have done in several cases, with some lengthening of life and avoidance of pain over what would have been gained by colotomy alone. But the cases which present themselves at this early stage are but a small minority of the whole, and in all others colotomy is the only proper treatment.

Colotomy is an operation which in suitable hands has scarcely any mortality, if performed early. In the last stages of the disease, unless complete obstruction is imminent, it may not be worth while to do it at all, for then there is a risk, as there would be in any other surgical interference, however trivial, and the patient will hardly live long enough to benefit. It is in the earlier stages of the disease that its greatest benefits are seen, when the tenesmus and frequent passages of bloody mucus are rapidly carrying the sufferer to the grave. Here we get the immediate relief of almost all suffering, the patient improves rapidly in health and weight, the frequent calls to empty the rectum are reduced to the passage of a little bloody mucus once or twice in twenty-four hours, and it is cruelty to try and impress upon the patient that he or she is not on the road to perfect recovery, as they sometimes fondly hope in spite of the clearest diagnosis and prognosis in the beginning.

Compared with extirpation, these results are most satisfactory and are obtained without risk. It is true we have not tried to cure; we have simply tried to prolong life by cutting off the diseased rectum from all part in the function of defecation, but in this we succeed and sometimes to a wonderful degree.

In the great majority of cases as they present themselves, colotomy is manifestly the only treatment. In a small number extirpation is indicated with equal clearness. But given twenty of the cases ordinarily considered suitable for extirpation, cases of annular carcinoma of the rectal pouch where the mass is still movable on subjacent tissues, and I am quite sure that a greater average length of life would be obtained by performing an early colotomy on all of them than by extirpation.

Charles B. Kelsey.

RESOPYRIN. The name given to a compound formed by the union of resorcin and antipyrine. It is obtained by the interaction of the two when mixed together in

molecular proportions; in solution, one part to three of water, an oily mass forms in abundance, which upon agitation changes into a hard, white, opaque body. It may be prepared from alcoholic solutions, in which it forms in rhombic crystals. It is odorless; insoluble in water; soluble in ether, one part in one hundred; in chloroform, one in thirty; in alcohol, one in five; in the latter menstruum it is not precipitated by the addition of water. Resopyrin differs chemically from resorcin by not giving a precipitate with lead subacetate, nor a blue color with ferric chloride. When heated it separates into an oily and an aqueous layer. It possesses the medicinal properties of both its constituents, but its therapeutic action is as yet undetermined. *Beaumont Small.*

RESORCIN. This drug is now rarely employed as an antipyretic in febrile disorders, as numerous unfavorable symptoms have been traced to its use, and many other more suitable antipyretics have been introduced. Its internal use is now directed particularly to its action as a stomachic and intestinal antiseptic. It is used in all forms of gastritis, dyspepsias following indiscretions in eating or drinking, in gastro-enteritis of children, cholera nostras, vomiting of pregnancy, sea-sickness, in gastric ulcer, and in cancerous disease. It is given in five-grain doses three times a day, and in addition to its antiseptic action it exerts a decided analgesic action, relieving pain and irritability of the stomach, and enabling it to retain food which otherwise would not be tolerated. Dr. Menche, of Bonn, who called attention to its use in digestive disorders, prepared a solution of three to five parts in a thousand; of this he gives to children one or two teaspoonfuls every two hours. A few drops of tincture of opium may be added if the relaxation is very marked. For adults the dose, as an intestinal antiseptic, is one and a half to two grains every two hours. It may be given in solution, or as a powder with sugar of milk. Only the resublimed resorcin should be employed for internal medication. A one per cent. solution has also been used to irrigate the stomach.

In addition to its general use as an antiseptic in the treatment of wounds, ulcerated surfaces, etc., it has been highly recommended as a topical application in diphtheria. A ten per cent. solution in glycerine is used, and this is applied to the diseased surface every hour during the day, and every two hours during the night. It acts by neutralizing the poison on the surface of the membrane, and by penetrating to the mucous membrane and lymphatics. It also is rapidly absorbed and counteracts the influence of the poison of the disease when present in the blood. The drug may also be used by diffusing in the room a twenty per cent. solution, by means of a spray.

The local application of an eighty to one hundred per cent. solution has been proposed in tuberculous ulcers of the pharynx and larynx, a five per cent. spray being used at the same time.

In pertussis it has been used with very remarkable success, the cough and paroxysms disappearing in four or five days. The treatment was introduced by Moncorvo, of Rio de Janeiro, and has been used with equally good results by others. A two per cent. aqueous solution is applied as a spray to nose, pharynx, and larynx, every two hours; the treatment should be continued for some time after the disease has developed. Its use also acts as a prophylactic, and prevents the disease from spreading to other inmates of the house. Some prefer to apply a one per cent. solution directly to the mucous membrane of the larynx.

In its use in general surgery and in diseases of the skin, it has been pointed out that weak solutions of one to three per cent. harden the skin, while stronger solutions, ten to fifty per cent., macerate and destroy it.

Beaumont Small.

RETINOL, RESINOL, ROSINOL. This substance, discovered in 1838, by Pelletier and Walter, has lately been recommended as a vehicle for various drugs. It is obtained by the destructive distillation of resin, which breaks up into four different bodies: retinpath, isomeric with toluene, and boiling at 108° C.; retinyle, isomeric with cumene, and boiling at 150° C.; retinol, which boils at 238° C.; and metanaphthalene, isomeric with naphthalene, and boiling at 235° C. Retinol has a formula of $C_{35}H_{16}$, and a density of 0.900; it is neutral in reaction, possessed of a slightly bitter taste, and has a faint peculiar odor similar to that of the fir-tree. It is of an oily consistence, pale yellow in color, resembling oil of sweet almonds. It contains a varying proportion of terebene, colophone, cresylol, phenol, and creosote. It is a very stable fluid, free from any irritating properties, and powerfully antiseptic.

Retinol has been administered internally as a remedy in septic fevers, in colds, bronchitis, laryngitis, and various other disorders of a catarrhal character, the quantity given ranging from a few drops to a teaspoonful. This use, however, has not been maintained. Locally it is a useful application to ulcers, wounds, diseases of the skin and of mucous membranes. It may be used as an ointment or applied as a tampon.

It is now employed as a solvent for numerous remedies which are insoluble in water and other ordinary vehicles. It mixes with fats, oils, glycerine, lanoline, carbolic acid, turpentine, alcohol, and ether, in all proportions; salol is soluble, one part in ten; naphthol, one part in fifty; aristol, one in fifty; camphor, one in twenty; chrysophanic acid, one in forty; cocaine, one in thirty. Resorcin, if dissolved in glycerine, may be mixed with it freely, and, so may iodoform if dissolved first in a little ether. Being unoxidizable, it is an excellent vehicle for phosphorus, a solution of which remains unchanged for an indefinite period. A solution is prepared by heating the retinol to 212° F. for a short time, and allowing it to cool in a clean dry bottle; to it one per cent. of dry phosphorus is added, which readily dissolves with the aid of a little heat.

One of the latest applications of retinol in combination with salol, is in the treatment of cystitis. The bladder is first irrigated with boric-acid solution, and then from two drachms to one ounce of a six per cent. solution of the salol in retinol is injected. The longer the solution is retained the better is the effect obtained; traces of it may be detected for several days. The treatment is applicable to various forms of cystitis, but its effect is most marked in chronic and subacute cases. In acute cases it may prove irritating and the solution be forcibly expelled. *Beaumont Small.*

RETRO-PERITONEAL TUMORS. Along the lines of study pursued by abdominal surgeons we can plainly trace the earnest work being done in an effort to clear up and place on a more secure footing this most difficult problem in surgery.

Whether success or failure is to be the result in this attempt, time only can solve. That it is a subject of much thought and earnest research at the present time cannot be denied. Thus far, investigations go to show that in the past there has been much confusion in the pathology of these growths, many errors in diagnosis, and not a very satisfactory record regarding operative interference. Like many other problems in this great field of surgery, an early, careful study of the case, a judicious weighing of all symptoms, subjective and objective, an experienced touch, no haste, are doing much to place on a more secure basis of classification these rare growths. Careful workers in the pathology of these tumors are doing much to clear up doubtful points, and establish on a more secure basis their true nature. Operating surgeons, when the tumor has obtained full size, have not found the work of removal at all encouraging, yet it is plainly to be observed that when the growth has been reached early, a percentage of recoveries has been secured hopeful for the future. The anatomical structure, the relations of the retro-peritoneal space, the physical changes that may occur, should claim careful study and review on the part of the surgeon who is working in this branch of surgery. The post-mortem table, the pathological laboratory, the microscope, have done much

to make clear the histology and pathology of these growths, and have given us knowledge that cannot be thrust aside ; and what seems an innocent development now, may very soon become serious in the establishing of true malignancy. Pressure, traumatisms, physical and mental periods of great exhaustion, all have their influence in making these cases go badly when once they have reached a certain size or period of development.

A careful study of retro-peritoneal tumors shows them to be of a mixed variety, containing the elements of both lipoma and myxoma tissues, which are, histologically, very closely associated. Fat is developed from embryonal mucin, and in post-fœtal life occupies those spaces in the economy which later in the fœtus are of myxomatous elements.

Again, in the retro-peritoneum both of these tissues are found, and doubtless many of these growths arise, under suitable conditions, from congenital neoplasms. There is, in these cases or classes of tumors, no inconsiderable amount of evidence to support the theory of Cohnheim relative to the origin of tumors. They are sometimes active in their growth, often become cystic, and at times reach immense proportions. Cases are reported of tumors of this kind weighing eighty pounds. The distribution of the elements is very diverse. The fat may be regularly distributed throughout the tumor or may occur as islands located here and there. These growths are very often œdematous, and by chemical analysis present a large percentage of mucin. The microscope, besides revealing the usual elements of lipoma and myxoma, very often reveals a numerous round-celled infiltration in the stroma of the growth, pointing to a sarcomatous element in their character. While not presenting all the features of active malignancy that carcinoma and sarcoma do, yet they often show a marked tendency to recur locally when removed.

Clinical histories and pathological research both show that tumors containing embryonal elements are very apt to be malignant, and can very truly be said to be always so.

The tumors found in the kidneys of young children are, for the most part, mixed tumors, chiefly myo-sarcoma. Many are surely congenital, and are an example of a new-growth developing from embryonal tissue. They have, by Grawitz, recently been compared to a series of embryonal growths which spring from the supra-renal capsules, and have the appearance of adipose tissue, but are usually sarcomatous. (Orth, "Pathologische Diagnostik.")

Even though the tumor may not at first present the condition of true malignancy, yet the operative surgeon has learned to know that the semi-malignant growth is very apt to return either in the cicatrix or the neighboring connective tissues, involving important structures, such as the large secreting glands or the lymphatics.

A careful investigation of the reported cases, together with an examination of all accessible works on pathology, impresses one that the most frequent origin of these growths is in the connective tissue of the capsular envelope of the kidney ; the next most frequent seat being the supra-renal capsules.

Mr. Hulke, of Middlesex Hospital, reports a case of myxoma surrounding the left kidney, which he operated upon. A median section was made through the tumor when it presented itself. The incision was continued through the posterior blade of the peritoneum, just beyond the descending colon. The tumor proved to be a myxoma, and, although the patient recovered from the operation, the growth returned locally. The kidney was not involved by the tumor, and could have been enucleated.

The growths embraced in this class are peculiar in several respects. None can be said to be absolutely benign, even those which are made up entirely of the histological elements of either lipoma, fibroma, or myxoma, and although they do not tend to the formation of metastases or to the infiltration of immediately surrounding tissues. It is true that they show no great tendency to recurrence when completely removed, yet from the great size to which they develop, and from their tendency to undergo degenerative changes, they cannot be classed as innocent growths.

Dr. John Homans, of Boston, has called attention in two papers to the reported cases of pure lipoma, among which were some on which he had himself operated.

Subserous lipomas rarely of themselves reach a large size. However, those going out from the peritoneum may be of sixty pounds' weight. Lipomas are usually slow-growing, the subserous particularly so. Subcutaneous lipomas sometimes grow rapidly after remaining stationary for years. Lipomas seldom change to other varieties. But they may primarily be mixed in character—myxo-lipomas.

The character of the latter group can never be determined with certainty without careful microscopical examination, as many growths having the appearance of lipomatous tissue often have the elements of myxoma and sarcoma as well. They may reach great size, but show no disposition to return after removal.

Sir Spencer Wells reports, in his first edition of "Abdominal Surgery," a case wherein the removal of such a growth was undertaken, with fatal results.

Sarcomas, either in typical form or in combination with myxomatous, lymphomatous, or fibromatous tissue, also occur, and have been observed quite often. Many of the tumors which have been described as sarcomas of the mesentery were doubtless retro-peritoneal sarcomas, arising at the root of the mesentery and presenting themselves anteriorly, after separating its folds.

Primary sarcoma springing from the mesentery is exceedingly rare. Sarcoma occurs most frequently in combination with myxomatous growths. These tumors are, histologically, very closely associated. Circulatory changes are likely to occur in them, viz., thromboses, with subsequent softening and cystic degeneration.

Carcinomas are very rare, and present the strongest type of malignancy. They are the hard, solid variety, soon forming deep and firm attachments, offering little to be hoped for from an operation. Varieties such as fibroma and cystoma have been observed. It may be said of the latter, for the most part, that they either spring from the walls of the pelvis, or from the subperitoneal connective tissue of that region. Virchow looks upon this series of growths as being analogous to those tumors which arise from the deep tissues of the neck.

A few remarks may be made in regard to the starting-point and relations of all these growths. Those which spring from the walls of the pelvis encroach upon or involve the bladder, uterus, and rectum, very often presenting features which are exceedingly perplexing in diagnosis. The origin of a smaller number is reported respectively as from the retro-peritoneal lymphatics, the bodies of the vertebræ and bones of the pelvis, and the root of the mesentery. In by far the greater proportion of the cases no exact origin is given ; indeed, from the subsequent changes in an atomical relations, it would seem quite impossible to determine the exact point of origin of many of the very large retro-peritoneal new-growths. They have almost uniformly presented themselves in the line of the least resistance, that is, anteriorly. In my case, reported in the *American Journal of the Medical Sciences*, January, 1892, the tumor presented itself in the back,—a condition which can be attributed to its origin from the extreme upper border of the kidney, where it was less completely bound down by the lumbar muscles and fascia. When the growths have reached a sufficient size to attract the attention of the patient, they are found presenting themselves at either side of the umbilicus, somewhere in the region of the lateral lines drawn in the arbitrary divisions of the abdomen into regions, although they may appear centrally. As the growths increase in size the viscera are displaced, not infrequently completely to the opposite side, although those growths which spring from the left kidney may have the descending colon externally. Owing to circulatory disturbances within them, and to their liability to a subsequent malignant infiltration, as well as to the development of cachectic conditions, they present, clinically, features which suggest a condition almost immediately hazardous to life.

As with any large abdominal growth, there is always a certain degree of encroachment upon the thorax and pressure upon other organs. In my second case, the tumor pushed the inferior border of the liver up to the fourth intercostal space, while the cæcum and ascending colon were displaced toward the left side of the abdomen.

Taking into consideration true retro-peritoneal tumors, it can be said of them they may have fat, connective tissue, fascia, muscle, or lymphatic tissue for their source. They may be homologous or heterologous in character. There can be no reasonable doubt that embryonal elements, which lie quiescent among the tissues, may, under suitable irritation, be a frequent source of their development.

Cysts have been reported by various authors as arising from the retro-peritoneum. Czerny reports particularly a case of dermoid cyst springing from the capsule of the kidney. Others have reported cases of similar growths springing from the walls of the pelvis, particularly in the neighborhood of the sacrum. The so-called cyst of the broad ligament is very often partially retro-peritoneal in character.

Whenever the physical examination reveals the character of the tumor to be a cyst, one should be exceedingly careful as to the diagnosis and prognosis. Retro-peritoneal cysts are exceedingly rare, are very likely to originate from infarctions in a more solid growth, and may be confounded with cysts from the parenchyma of the kidney or from the pancreas.

Diagnosis.—Notwithstanding our constantly increasing experience in abdominal surgery, we must admit that an exact diagnosis as to the true nature of these growths is not always possible. Nor can it be said to be absolutely necessary, especially in the lesser and more movable varieties.

I cannot well imagine a more severe task for a writer than to attempt to outline the symptoms and diagnosis of a condition which, until the present time, has baffled, quite without exception, the skill of all who have met with it. Yet, recognizing the importance of the factor of exact diagnosis, especially in abdominal surgery, I wish to call attention to all such symptoms as may be associated with these growths, and, after carefully weighing them, put together what seems useful.

In the first place, there is not a single symptom that is pathognomonic, and we are dependent for diagnosis upon the process by exclusion. Diseases and neoplasms of the uterus and its appendages, of the liver and the gall-bladder, of the spleen, pancreas, and kidney, are to be excluded, as well as aneurism of the aorta, tumors of the mesentery, and of the abdominal walls.

Sex or the history of the case may enable one to exclude the organs of generation at once, and bimanual examination will rarely fail to locate the uterus and its appendages and determine any pathological changes in them. Pelvic congenital cysts from the spinal cord or membranes should not be lost sight of. Subperitoneal fibroids are the only ones likely to be confounded with this condition; but, then, uterine fibromas are more easily movable within the abdomen, and their attachment to the uterus can be made out. Solid tumors of the ovary and broad ligament present greater difficulties, which at times cannot be surmounted.

Diseases of the liver, together with new-growths of that organ, have very often been mistaken for retro-peritoneal neoplasms. Hypertrophic cirrhosis, amyloid degeneration, hepatic abscess, hydatids, obstruction of the cystic duct, and distention of the gall-bladder, together with carcinoma and sarcoma, present physical signs which may be confounded with retro-peritoneal tumors. The history of the case, together with a painstaking weighing of general symptoms, will naturally assist in clearing a doubtful diagnosis.

Disturbances of biliary excretion may occur from pressure on the common duct by the tumor. Again, tumors of the liver always move synchronously with the respiration. Retro-peritoneal ones do not, as a rule. Very often a line of resonance is found between liver and tumor, which at once shows that the growth is not connected with the former organ.

My own experience teaches me that growths connected with the spleen make the case at times very embarrassing.

It has been said that the differentiation from hypertrophy and tumors of the spleen presents less difficulty than does the differentiation from tumors of the liver. Here palpation and percussion will be quite sufficient, if employed to locate the spleen in its normal position. Tumors of the omentum lack the fixed position of these growths. The absence of digestive disturbances, with fatty stools, will serve to exclude the rare new-growths of the pancreas.

As stated, many of these tumors have their origin in the capsule of the kidney, or in the connective tissues surrounding it. They present, at least in their earlier stages, physical signs differing in no respect from tumors of the nephritic parenchyma. An examination of the urine may give an exact clue to the diagnosis. In none of the cases reported had renal hæmorrhage or albuminuria, with or without casts, occurred; conditions which are the rule with tumors of the parenchyma of the kidney.

Regarding the use of the aspirator, while I must admit that up to the present time it has been of no especial value in the diagnosis of my cases, yet I believe that in many instances the fluid withdrawn by this instrument and carefully examined, would enable us to make a diagnosis as to classification of the tumor. In a recent case of sarcoma of the kidney, by means of the medium-sized needle I was able to draw off sufficient fluid to fully demonstrate the nature of the growth, the diagnosis being confirmed later by the autopsy. All things considered, I believe the instrument is of value in the diagnosis of retro-peritoneal tumors.

The suggestion made by Dr. W. G. Macdonald, of rectal insufflation of hydrogen gas, I believe worthy of trial, especially where a careful examination has been made before, and the percussion areas have been outlined with care upon the abdomen. The process of insufflation should be carefully watched, that the relation of the intestinal tube to the tumor may be established.

One should be very cautious, particularly if in doubt regarding new-growths springing from the pancreas, or from the surface of the kidney on the inner side. A growth springing from the latter position is, as I have intimated, likely to present some pathological evidence in the urine.

Treatment.—Without operative interference there is but one termination. The rapidity of the fatal termination varies somewhat with the character of the growth. Pure lipomas are slow-growing until a certain volume is reached, when they proceed with great rapidity to a fatal termination. From a study of the clinical histories found in the literature, I am of opinion that the mean duration of life, after the discovery of the tumor, is not more than nine months. Operative treatment offers to us much promise. Recovery has followed the removal of retro-peritoneal tumors of great weight, even those weighing fifty pounds. The immediate mortality following operations is great, from necessity; yet from the hopelessness of the conditions an operation is to be urged with great earnestness upon the part of the surgeon. Incomplete operations have been immediately more fatal than those in which the tumor has been completely removed. Like all surgical lesions, these tumors illustrate the necessity of early diagnosis and prompt operation.

Czerny, in concluding a paper in which he had reported three cases, says: "In all cases operative interference can be safely undertaken; that when the tumor is no longer encapsulated, the incision had better be closed, otherwise the growth should be enucleated."

Operations for the removal of retro-peritoneal growths will, from necessity, be subjected to considerable modification in detail. The choice of incision will usually fall in the line of the linea semi-lunaris, on one side or the other; Langenbeck's incision for removal of the kidney may be made use of. Frequently, when the incision is at first exploratory it must be made in the median line. When the anatomical relations can be

made out, and the operation continued by an extension of the cut, then the more favorable incision is in the linea semi-lunaris. By the separation of the peritoneum from the internal border of the tumor, it may be attached by sutures to the internal border of the abdominal wound, making the whole field of the operation extra-peritoneal.

The incision of the posterior fold or blade of the peritoneum should be external to the attachment of the mesentery of the colon, although this is not absolutely necessary. The removal of the growth by enucleation must be accomplished with great care; particularly is it always desirable to determine the source of the blood-supply and its relations to the great vessels. The vena cava has been wounded by accident in the enucleation of these growths. There are likely to be large, thin-walled veins located deeply in the wound, requiring ligation. It will be found at times necessary to remove the kidney with the tumor, and here the danger of hæmorrhage is very great. The supply-vessels of the kidney will frequently be found very short and difficult to reach.

The length of time required for the performance of the operation will vary, necessarily. As long a time as two and one-half hours has been consumed in a difficult operation. As in all strictly abdominal work, the operator must be prepared for any and every possible complication.

After enucleation, as well as when the kidney has been removed with the growth, the cavity must be thoroughly drained, either by full-sized drainage-tubes or by iodoform tamponade.

The after-treatment presents no indications for management other than those of a severe case of abdominal section.

As in all other conditions in surgery, there is certainly at the present time a better understanding of these cases. A more correct and early diagnosis, as is the case in all that pertains to medicine and surgery, will surely bring a larger percentage of recoveries.

These are purely surgical cases; no medicines, no mineral waters, or baths, electricity, or other lines of therapeutics, have as yet been of any service.

RHEUMATISM, ACUTE. Great differences of opinion still exist as to the cases which should be placed under the head of "Acute Rheumatism." Immerman, in this connection, quotes the couplet:

> "Was man nicht definiren kann,
> Das sieht man als Rheumatismus an."

It is therefore necessary, in treating of this subject, first to decide the pathological conditions which may properly be included under the head of rheumatism. These may be given as follows:

1. Those typical cases of acute arthritis which are accompanied by fever, and in which there is a special tendency to inflammation of the membranes of the heart.

2. Atypical cases, such as those of acute muscular rheumatism, polyarthritis sine arthritide, cases of chorea of evident rheumatic origin, cases of larval rheumatism such as are described by Immermann.[1] The same author also includes[2] under the head rheumatism spastic forms of disease which affect the distribution of the accessory nerve of Willis. Edlefsen,[3] through his pupil, Classen, expresses the opinion that forms of neuralgia not due to central nervous disease, meningitis, or syphilis, are also of rheumatic character.

Friedländer[4] includes Landry's acute ascending paralysis, acute anterior polio-myelitis of the adult, acute bulbar paralysis, some cases of Basedow's disease, tetany, diabetes insipidus, and diabetes mellitus. Hirsch is of opinion that many of the cases of cold attended by pains in the limbs are really of rheumatic character.

Rehm and Immerman deny the identity of scarlatinal rheumatism with the typical disease, whereas Edlefsen and Strick consider the poisons identical.

Hirsch is opposed to the identity of the two conditions. Senator[5] excludes the following conditions: gonorrhœal rheumatism, that accompanying bronchiectasis and hæmophilia, as well as peliosis rheumatica. Painful conditions of the muscles after over-exertion, when persistent, are in the writer's opinion of rheumatic character. This, however, is denied by some. Pleurisy is sometimes, and tonsillitis often, of rheumatic character.

Although not willing to go to the length of some of the German authorities, the writer concludes, from clinical experience, that the rheumatic poison may be the main etiological factor in many diseases which have not so far been considered of rheumatic character.

ETIOLOGY.—Since 1885 very much has been written upon the etiology of acute articular rheumatism, and it may be safely said, notwithstanding the fact that the micro-organism peculiar to this disease has not yet been positively made out, that the belief is growing stronger and stronger that acute rheumatism is an infectious disease, and that the special microbe will in time be discovered.

Dr. T. J. MacLagan, in his exhaustive work upon this subject, published in 1886, arrived at the following conclusions: 1. Rheumatic poison is malarial in its nature. 2. Malarial poison is an organism, and therefore allied to the contagia. 3. That both poisons exhibit the phenomena of those which owe their morbific condition to their organic development within the system.

Since the publication of this work the organism of malarial fever has been discovered by Laveran, and the discovery confirmed by Councilman, Osler and others, so that the second conclusion has been thoroughly substantiated. The third conclusion, so far as it relates to malarial poison being reproduced in the blood, has also been thoroughly verified by subsequent discovery. Although no organism has yet been discovered which with certainty can be said to be the cause of rheumatism, bacteria have been found in many cases. Wilson [6] discovered a short bacillus in two cases of rheumatic pericarditis. Petrone [7] drew fluid from a rheumatic joint, and found a bacillus similar to that described by Klebs. Guttman's [8] case was probably of a pyæmic as well as of a rheumatic character. He found an organism similar to the staphylococcus pyogenes aureus.

Mantle [9] found two forms of micro-organisms: (1) micrococci grouped in diplococci, (2) a short thick bacillus. Leyden [10] found similar micrococci. Jaccoud [11] was unable to find micro-organisms, but Bordas, in G. Sée's clinic, found them in two out of six cases. The microbe he describes is a bacillus cultivated readily in peptone gelatine, in tubes or on plates, and still more readily in veal broth. In two instances the injection of this culture produced rise of temperature in the rabbit, and in one was followed by endocarditis with vegetations on the valves. Popow also discovered micrococci.

Dr. Angel Money [12] is of opinion that rheumatic fever is a blood-poisoning from fatigue products, the result of nitrogenous tissue metamorphosis, and the nervous system forms the secondary element in the etiology. In this connection it is interesting to know that Dr. B. W. Richardson [13] affirms the conclusion he arrived at a number of years ago in the following words: "The inference is as clear to me now as it ever was, that the secondary action of lactic acid as a cause of rheumatism is proved."

Pel,[14] of Amsterdam, expresses the opinion that the disease is of miasmatic origin, and that its frequency bears an inverse proportion to that of malaria.

The investigations made into the statistics, as well as the surroundings of rheumatic patients, afford more conclusive proof of the infectious character of the rheumatic poison than that given by the bacteriologist.

Edlefsen [15] found that laryngitis and acute bronchitis, diseases which are usually supposed to be the result of exposure to cold, were in point of frequency in inverse ratio to rheumatism, showing that the latter disease was not produced by exposure alone. He also published statistics to prove that rheumatism is a house disease, many cases occuring successively in the same house. Similarly to pneumonia and malarial fever, rheumatism is always more prevalent when the soil is drying up, and less frequent during continuous rainfalls. These facts seem to show that the rheumatic poison is a miasm, and that it exists in the soil.

Jürgensen confirmed these observations, especially the fact that it is a disease often found in certain overcrowded homes. Hirsch found that in only twenty-four per cent. of rheumatic cases were there evidences of exposure to cold. Feltkampf has made similar observations on the meteorological conditions during the prevalence of rheumatism. Mantle also found that in a large percentage of cases there was no history of taking cold

Hirsch arrives at the following conclusions: 1. Acute rheumatism is not a disease produced by cold. 2. Acute rheumatism is to be placed among the malarial diseases, for the following reasons: *a.* The greater number of cases occur when the soil is drying up, and a less number during a heavy rainfall. *b.* The virus seems to exist in greater amount in certain houses or localities. Some cases have been reported which seem to show that rheumatism is at times a contagious disease. Mantle mentions a case, and Schaefer gives an instance of the disease in a newly-born child when the mother was suffering from rheumatism. Friedländer states that in the Leipsic clinic patients coming into the hospital with other diseases, have afterward acquired rheumatism. In the same clinic, the celebrated Wagner at one time had the rheumatic cases isolated. Feltkampf gave an instance in which a convalescent from typhoid acquired rheumatism from two other patients in the same ward.

Jaccoud gives two instances where infants born at full term while their mothers were suffering from rheumatism, manifested symptoms of the disease. In one case in twelve hours, and in the other in three days, the infants were seized with well-marked acute articular rheumatism.

The metastatic character of rheumatism, as for instance where it is associated with thrombi, emboli, endocarditis, pericarditis, and brain lesions, points to its being an infectious disease. Then the appearance of the internal viscera after death is very similar to that found in cases of septicæmia: such as small hæmorrhages beneath the serous membranes, enlargement and softening of the spleen, etc. All are agreed that the predisposing causes to rheumatism, are debility from overwork, physical or mental, heredity, and exposure to cold. Men are more frequently attacked than women: three hundred and seventy-five males to two hundred and seventy-nine females, as shown by the report made by Whipham [16] to the British Medical Association. It occurs more frequently in females up to the age of twenty. It may occur at any age. Robert Bell, of Glasgow, expresses the opinion that chronic constipation is an important predisposing cause.

Clinical History.—It is not necessary here to repeat the well-known symptoms of a case of typical acute rheumatic arthritis, but simply to refer to those features to which attention has of late been drawn.

Jaksch has found peptones in the urine in twelve cases of rheumatism. Cystin is sometimes found. There is a rapid diminution of the red corpuscles in the blood and an excess of the white. Salmonson found excessive lactic acid in the blood. Cases of rheumatism have been reported in which all the joints of the body, even those of the vertebral column, have been affected.

Angel Money [17] made a systematic investigation of the cutaneous sensibility over affected joints. The acuteness of tactile sensation was found much increased, and the power of localization disturbed. Complete analgesia was at times a marked phenomenon, which might perhaps have been of a hysterical nature. The sensation of cold was usually diminished, and that of heat increased.

Faradic sensibility was diminished or abolished near the joint, and sometimes over the whole limb.

I will not again refer to the atypical cases, which are in all probability of rheumatic origin, as they have already been mentioned in the introduction to this article.

Dr. W. S. Church [18] gives the following conclusions after the study of nearly seven hundred cases. These are of special interest in connection with the prevalence of heart lesion in acute rheumatism. 1. Men suffer in somewhat larger numbers and more severely than women. 2. More than half of those affected have some cardiac lesion in their first attacks, and more than two-thirds of those who suffer from a second attack are found to have old or recent endocarditis. 3. Endocarditis attacks men and women almost equally. 4. Men suffer more than twice as frequently from pericarditis as women. 5. The heart when affected is usually implicated within the first week of the attack. 6. The liability to cardiac affection diminishes with age.

If we accept Immerman's conclusion, the condition of hyperpyrexia can be easily explained by assuming the heat centre to be especially affected in such cases. High temperature has been observed in many cases some hours after death. Brain delirium and stupor are frequently found in cases of hyperpyrexia. A peculiar form of delirium which was dwelt upon at length by Sir Thomas Watson in his lectures on the "Practice of Medicine," is found in many cases of pericarditis.

Meningitis, although sometimes present, is rare in acute rheumatism. When, however, as in ulcerative endocarditis, a septic element is introduced, meningitis is much more frequent. Convulsions and coma are sometimes the result of uræmia from nephritic complications.

According to Dr. Church's observations, lung complications are now much less frequent and much less severe than formerly.

Barlow [19] and Warren have first directed attention to small round, subcutaneous tumors, varying in size from a shot to a small pea, found most frequently on the fingers, hands, wrists, and along the spine. A case in Dr. Osler's clinic, presenting this complication, has been reported by Dr. J. K. Mitchell.[20] Dr. McPhedran, of Toronto, has reported two cases.

According to Dr. Cheadle, they are not at all uncommon in children. They are made up of recently formed fibrous tissue, and are no doubt of rheumatic origin.

In this connection I would refer to two cases of circumscribed œdema, which I have observed in connection with marked rheumatic symptoms. The skin affections which are most frequently found in connection with rheumatism are erythema multiforme and nodosum, urticaria, herpes facialis, and hyperhydrosis. The evidence in favor of the close connection between the erythema and rheumatism has been summed up as follows by Garrod: [21] 1. Both E. multiforme and E. nodosum occasionally appear in direct association with rheumatic fever. 2. They are usually attended by some degree of arthritis. 3. The arthritis which accompanies erythema may have any degree of intensity, from the severest joint lesion of acute rheumatism to the slightest joint pain. 4. Collateral evidence, such as the presence of chorea or old heart lesion, is sometimes obtained, pointing to the rheumatic nature of the slightest joint lesions. 5. Acute cardiac lesions may accompany erythema with the slightest arthritis, and probably sometimes occur in the absence of joint symptoms. 6. Erythema without joint lesion is uot uncommonly met with in patients who have previously suffered from rheumatism, but in some cases there is no evidence of association with that disease. We are uot therefore justified in concluding that such symptoms are always rheumatic.

Brocq is probably right when he states in his treatise on dermatology that erythema is an expression of the rheumatic poison in the same way as it may be produced in other infectious conditions.

Six cases of jaundice occurring in acute rheumatism have been reported by Leiblinger.[22]

Friedlnäder has divided cases of acute rheumatism into two classes, central and peripheral. In the former the brain, medulla, or cord may be affected, whereas in the latter the typical lesions are found in the joints.

Latham in his Croonian Lectures expressed the opinion that the phenomena of rheumatism, gout, and diabetes, depended on the condition of the nervous system.

According to Friedländer, there is a regularity in the length of time the fever lasts, as well as in its course. There may be but one cycle, lasting from eight to eleven days, or there may be a series of such cycles, one following the other. The fever and the arthritis begin and end at the same time. Hirsch in his observations was not able to discover any such rise and fall of temperature, nor do I think that such regularity has been shown in cases observed by me.

Dr. J. E. Atkinson, in a paper read at the meeting of the Association of American Physicians, 1891, on Bradycardia in Acute Rheumatism, arrived at the following conclusions: 1. Bradycardia is observed rarely during the active stage of acute rheumatism (inflammatory). It occurs with greater frequency during convalescence from the disease. 2. When it occurs during convalescence, probably in most cases it is identical with bradycardia following acute febrile diseases of widely different nature, and is directly the result of the febrile action itself upon the innervation of the musculature of the heart. 3. When it occurs during the active stage of rheumatic fever, it probably depends upon endocarditis, or pericarditis, or myocarditis (primary or secondary by extension), whereby the inhibitory nerves of the heart are implicated, and consequently stimulated. Even where the physical signs of cardiac inflammation are absent, bradycardia occurring during the acute stage of rheumatism may be secondary to undetected myocarditis stimulating the vagus nerve. 4. It is possible, but exceedingly improbable, that these symptoms may follow the action of the rheumatic noxa upon the cardiac muscle or nervous system directly.

The diagnosis of typical cases of acute rheumatism is easy, but it is often extremely difficult in atypical cases to say whether they are of rheumatic character or not.

Immerman speaks highly of the curative effects of the salicyl compounds, as a means of diagnosis in these cases. It is not always easy to make a diagnosis between acute necrosis, or acute osteo-myelitis and rheumatism in the earlier stages. The diagnosis too is of very great importance, owing to the difference in treatment. The greater intensity of the constitutional symptoms, the tendency of the inflammation to centre in one locality, and the involvement of the epiphyses rather than the synovial membranes, are great aids in coming to a correct conclusion.

During the past year a case of suppurative synovitis of the knee-joint which I had under observation, presented great difficulty in diagnosis during the first week. The fact that the inflammation is confined to one joint should make us pause before giving a diagnosis of rheumatism.

TREATMENT.—The salicyl compounds are still the principal remedies in the treatment of acute rheumatism. Much difference of opiuion exists as to whether these remedies are curative or simply palliative. Dr. McLagan, who preferred salicin on account of its producing a less depressing effect upon the heart's action, has spoken of it in the following terms: "Given then at the commencement of the attack, it seems sometimes to arrest the course of the malady as effectively as quinine cures an ague, or ipecac a dysentery." He was in the habit of giving very large doses, as much as an ounce in the first twenty-four hours.

Dr. James Martin [23] relates a case treated by a mixture of fl. ext. cascara and soda salicylate, with excellent results after the salicylate alone had failed. Dr. Goodwin,[24] of New York, also speaks highly of cascara in the same combination. Senator, as the result of lengthened observations on the treatment of rheumatism, considers the salicylate to be somewhat disappointing. He recommends antipyrine, autifebrin, phenacetin, and salol, as remedies which will act as specifics in the management of rheumatism. In the use of these remedies, it is necessary to individualize, as often one will succeed where another fails. If we understood the correct method of individualizing, he thinks with three or four remedies we would be successful in every case. Salol, discovered by Nencki, and first used by Sahli,[25] in presence of the pancreatic ferment divides into carbolic and salicylic acids, its component parts. Sahli thought salol had a more favorable effect in preventing cardiac complications than the salicylates.

Herrlich,[26] in Leyden's clinic, tried salol in thirty cases. He was favorably impressed with the results, but does not think it prevents endocarditis.

Dr. Church, in the report already alluded to, recommends the following remedies: alkalies, salicylates, and antipyrine. He recommends light clothing so as to lessen the fever and excessive perspiration. He is careful not to allow the patient to return too soon to a meat diet.

Dr. Osler recommends the oil of wintergreen, which he gives in twenty-minim doses every hour in milk.

Donald W. C. Wood gives statistics of 850 cases of acute rheumatism treated at Guy's and St. Bartholomew's, from which the conclusion is drawn that the salicyl compounds are as a general rule effectual in obtaining early relief from pain, and reducing temperature, but that they exert little or no influence over the duration of the disease.

Professor Benedikt claims to have obtained good re-

sults from the hypodermic injection of a solution of carbolic acid. Fränkel and N. S. Davis speak highly of the value of antipyrine. M. Vulpian recommends the salicylate of lithium in fifteen-grain doses, to be given four or five times in twenty-four hours. The salicylates, as has been shown, are not specifics for rheumatism, nor have any yet been discovered. The evidence of statistics taken from a very wide field proves that the duration of the disease is not lessened, nor do they prevent complications, and that relapses occur more frequently when they are used. Cheadle thinks the salicylates should be sparingly used in the rheumatism of children. In the prophylaxis of the disease, it is necessary to avoid exposure to cold and dampness, which we know by experience to act so frequently as a predisposing cause. Although I am quite convinced of the infectious character of the disease, the clinical history proves that, like pneumonia, exposure renders the system much more liable to become affected. *James E. Graham.*

RIPPOLDSAU. A mineral water and climatic station situated in the Black Forest, Germany.

LOCATION.—The little village of Rippoldsau is picturesquely located in a narrow valley of the Black Forest of Baden. A small stream, the Wolf, flows through this valley, and the pine-clad hills afford adequate protection from harsh winds. The climate is pleasantly invigorating, the air being pure and sub-alpine in character. The altitude of this rather fashionable resort is 2,000 feet above sea-level. The season extends from May to September. According to Bradshaw ("Climatic Health-resorts"), "the scenery is wild and romantic, precipices, ravines, and waterfalls alternate with meadows and pleasant homesteads, on the borders of an ubiquitous pine forest. Rippoldsau is one of those spots which, though easy enough of access, convey to the visitor the sensation of being at an infinite distance from the turmoil of cities and civilized life. Though nature has so amply provided for this beautiful spot, art has also aided. The gardens, avenues of trees, parks, and walks over the hills have been laid out with great care and skill. All things considered, Rippoldsau is the spot in which to pass a few weeks in summer, for rest and retirement, apart from all considerations of health.

"Some portions of the bathing establishment are modern, while others preserve their original and archaic characters.

"The excursions are very varied, and extend through the whole Black Forest. Amusements are likewise provided for; a Bohemian band plays three times daily. The buildings are all connected by covered passages, and communicate by means of electric bells. They contain large dining-rooms, ladies' room, music, coffee, reading, smoking and billiard rooms, and a large lawn tennis ground. Balls and dances are given from time to time."

ANALYSIS.—The mineral springs have the average composition of mild saline chalybeate waters.

INDICATIONS.—The place is chiefly visited by patients with anæmia, chlorosis, neurasthenia, hysteria, and moderately severe pulmonary and digestive disturbances. Consumptives are also sent there, but it does not appear that they are likely to do remarkably well there, the place being small and crowded.

ACCOMMODATIONS.—An excellent, but expensive, hotel is found here, there are facilities for hydrotherapy, milk and whey cures, pine-needle baths, etc.

E. C. Wendt.

ROYAT-LES-BAINS.—This celebrated French spa has already been briefly referred to in Vol. VI. of the HANDBOOK. Its intrinsic importance as a watering place, and the fact that many Americans now take the waters there, justify some additional information concerning its special features. According to Dr. Vintras ("Mineral Waters of France"), "the Thermal Establishment, one of the finest and most complete in France, stands in the most picturesque part of the valley, between the right bank of the Tiretaine and the road which leads from Royat to Mont-Dore. It includes no fewer than ninety-four bath-rooms, with baths of stone, each provided with apparatus for local douches, vaginal, articular, etc. It has, besides, independent apparatus for douches of various forms, two inhaling-rooms, a large public swimming bath traversed by a current of fresh water, which is reserved for ladies in the morning, and for men in the afternoon; arrangements for carbonic-acid baths and douches, as well as for the water-cure system, and lastly a gymnasium."

Dr. Brandt, in the *Climatologist*, January 15, 1892, gives an excellent account of Royat. He states that "the discovery of the Saint Victor spring, buried under the old Roman Piscina, showing in its analysis a considerable amount of arsenic and iron in combination with the salts contained in the other springs, found its application in those cases of anæmia, chlorosis, lymphatism, and general debility, which now crowd to Royat. It is only of late years that cases of gouty glycosuria, neurasthenia, and a few suffering from myxœdema, found benefit from the use of this spring. It is well to remind the reader that among the arthritic there are some cases that do better than others. The asthenic gouty are those which derive most benefit, and what is popularly called 'Poor man's gout' is the type most suited for a Royat cure; for it stands to reason that a water containing iron and arsenic is better adapted to an anæmic subject than to a plethoric beef-eater.

"If we add to the curative properties of these waters the effects of rest from all mental work, the delightful rambles through wooded vales, inhaling a pure dry air scented with the refreshing perfume of wild flowers, we shall have a complete *résumé* of the benefits that Royat-les-Bains can offer.

"For those who are fond of mundane pleasures, the company provides an excellent orchestra, which plays in the park three times a day; also a casino with its theatre, reading, and card-rooms, where the idler can amuse himself *ad libitum*. The proximity of the old town of Clermont-Ferrand affords the rambler many pleasant hours for studying the antiquated buildings—the cathedral, the old churches, museum, and many other places of interest.

"Royat is at a reasonable distance from Paris. The Paris-Lyons and Mediterranean Railway Company starts two daily express trains to Clermont-Ferrand—one in the morning, the other in the evening. The former is the one generally preferred, as it lands its passengers in good time for dinner. The journey takes nine hours."

In regard to the climatic peculiarities of Royat, Dr. Yeo ("Climate and Health-resorts") is authority for the following: "Its climate depends partly on its adjacency to the great central mountain chains of Auvergne, the Monts Dômes, and the Monts Dore, partly on the porous volcanic soil, and partly on its own particular situation. To the first it owes its sudden storms of wind and thun-

der and rain, and its sudden transitions of temperature —the characteristics, in short, of a mountain climate of moderate elevation. To its volcanic soil it owes the clouds of black and reddish dust which are blown about in eddies by the sudden gusts of wind, as well as the dryness of its roads and also the dryness of its atmosphere, this dryness of atmosphere being a most important climatic condition, counteracting the ill effects of the storms of wind and rain. Then there is the peculiar situation of Royat itself. Lying as it does in the floor of a somewhat narrow valley, surrounded on all sides by mountains, and only open to the east; running, moreover, in a direction exactly east and west, and facing the east, it is particularly exposed to the direct heat of the sun. From the moment the sun rises in the east above the mountains of Forez until it sets in the west behind the gigantic mass of the Puy-de-Dôme, Royat lies exposed to its rays; and it is therefore exceedingly difficult to find any kind of shady walks in the immediate vicinity of Royat when the sun is up and the sky is cloudless. Generally, however, when the sun goes down, the cooler upper strata of air rush down from the higher plateaux into the valley, and thus you get cool, refreshing currents of air playing through the valley on the evenings of even some of the hottest days in summer."

According to the recent analysis by M. Willm, chief of the chemical laboratory of the Medical Faculty of Paris, 1,000 grammes of the water contain :—

There is also found arseniate of soda in Source César, 0.0008 grm.; St. Mart, 0.0016 grm.; St.-Victor, 0.0045 grm.

The hotel and other accommodations offered at Royat, are quite good, and the spa undoubtedly deserves the great popularity which it now enjoys.

Edmund C. Wendt.

RUBIDIUM AND AMMONIUM BROMIDE.—A double salt having the chemical formula $RbBr, 3NH_4,Br$. It is a white or yellowish-white crystalline powder, soluble in water, and possessed of a cooling and saline taste.

This salt has been proposed as a more suitable means of administering bromine than the ordinary ammonium, potassium, or sodium salts. Laufenauer (*Therap. Monatsch.*, August, 1889), reasoning from the fact that lithium bromide is more powerful than ammonium bromide, the sodium salt more so than the lithium, and the potassium salt still more powerful, was led to believe that the more strongly electro-positive the salt, and the higher its atomic weight, the greater its power in disease. As rubidium is powerfully electro-positive and has a high atomic weight, the bromide of rubidium and ammonium was prepared, and in a series of experiments was found to prove more satisfactory than the other bromides in epilepsy and other conditions in which bromides are indicated.

Further use of the drug has proved its efficacy, but has not shown any decided advantage over other bromides. It, however, has not the depressing effects of the potassium salts, and may be given where the more common compound has to be discontinued. As an antiepileptic remedy, it is given in doses of sixty to ninety grains in divided doses. As a hypnotic and sedative, sixty grains may be given in a single dose.

Beaumont Small.

SACCHARIN.—After a great deal of discussion and controversy, this compound has found its position in our materia medica as a harmless drug, its sole use being to replace sugar as a sweetening agent. For some time it was thought to exercise an injurious effect on the system, in consequence of which the governments of France and Spain prohibited its use except under the supervision of a physician. It is now regarded as perfectly harmless, and any injurious action is to be explained by the presence of other compounds formed during its preparation. It has been given to animals for a prolonged period, without producing any effect upon the organs or upon the processes of nutrition. It passes through the body unchanged and is wholly excreted by the kidneys.

Saccharin has been placed in the pharmacopœia under the title of Glusidum. It is a light, white, minutely crystalline powder, odorless but with an intensely sweet taste. It is soluble in water to the extent of one part in five hundred; in rectified spirit, one part in thirty-five; in proof spirit, one part in eighty; in glycerine, one part in fifty. Its solution gives an acid reaction, and it forms sweet salts with alkaloids and metals. When fused with potash or soda, it is decomposed and partially converted into salicylic acid, forming salicylates of potassium or sodium. Its property of combining with alkaloids is taken advantage of to supply quinine and other bitter substances in a more palatable form. The insolubility of gluside is overcome by combining it with soda to form a soda salt which is very soluble. It may be prepared by dissolving one hundred parts in water and neutralizing the solution with bicarbonate of soda and evaporating to dryness; this forms one hundred and thirteen parts of soluble gluside.

Excepting in its sweetening power, gluside is not allied to sugar in any way. It does not affect polarized light, it lacks the essential character of sugar to produce alcohol by fermentation, and when administered does not increase the production of sugar in the system. It is this latter quality that renders it of value in the treatment of diabetes, where it is desired to avoid the use of sugar as far as possible. No dose is applicable to this purpose, as the quantity required must of necessity vary greatly. Five, ten, or fifteen grains will generally be found sufficient, but as much as fifty or eighty have been given daily without any undesirable effect, excepting a distaste and nausea.

Gluside is two hundred and eighty times as sweet as sugar, and if it is remembered that an ordinary lump of sugar ranges from 150 to 300 grains, it is very evident that one-half to one grain will be an equivalent. Its disadvantages are the distaste that the patients are liable to have for it after using it for a time, and the dry, acrid sensation it produces in the pharynx. In medicines, it may also be used to replace sugar and syrup for the purpose of rendering them palatable, one grain with a six-ounce mixture furnishing sweetness equal to one ounce of ordinary syrup. To facilitate dispensing, the following solutions are prepared.

Liquor Glusidi.—From the "National Formulary" of the American Pharmaceutical Association. Gluside, 512 grains; bicarbonate of sodium, 240 grains; alcohol, 4 fluid ounces; water, sufficient to produce 16 fluid ounces. Each drachm represents four grains of gluside.

Elixir Glusidi.—From the "Unofficial Formulary" of the British Pharmaceutical Conference. Gluside, 480 grains; bicarbonate of sodium, 240 grains; rectified spirit, 2½ fluid ounces; distilled water a sufficiency.

Rub the gluside and the bicarbonate of sodium in a mortar, with half a pint of distilled water gradually added. When dissolved, add the spirit, filter and wash the filter with sufficient distilled water to make one pint. Each drachm represents three grains.

Gluside possesses antiseptic properties in common with other coal-tar derivatives, and for this reason it has been suggested as a remedy in many diseases. It has been used in pulmonary phthisis, acute articular rheumatism, scarlatina, intestinal catarrh, cystitis, and a number of other disorders in which its antiseptic action might prove of service. Of these, cystitis is the only one in which any satisfactory results have been obtained. In this condition it is administered internally and renders the urine antiseptic during its excretion. When there is pus and an alkaline reaction, this is rapidly overcome, and the urine becomes clear and normal in character; the change in the urine being accompanied by a corresponding improvement in the mucous membrane of the bladder. Three grains, in divided doses, daily, is the quantity recommended, and this is to be continued for a prolonged period. The bladder may also be irrigated at the same time. *Beaumont Small.*

SACRO-ILIAC DISEASE. Some of the later anatomists deny the presence of a synovial membrane at this joint. If there be no such membrane it disposes of the question whether the disease ever begins as a synovitis. From clinical observation it has long been our belief that tubercular disease at this joint in children invariably commences as an osteitis. We have seen none of the traumatic cases in young cavalrymen, nor have we met with the septic and gonorrhœal cases reported by others, which cases would argue the presence of synovial tissue.

The diagnosis is at times extremely difficult. Early in the disease the symptoms are few and indefinite; later, the sensitiveness at the joint may become so intense that both lumbar spine and hip-joint are held rigid, to better fix this articulation. Theoretically, forward and lateral bending of the spine should be free, and only backward bending restricted; in the same way at the hip, only extension and inward rotation during full extension should be limited; but we have met with cases so sensitive for a time that motion at the hip, as well as in the lumbar spine, was absolutely abolished.

The operative treatment of sacro-iliac tuberculosis has more justification than has the same treatment at any other joint. The joint is readily reached, and, unless extensive, the disease can be excised without risking any important structure. Recovery should be rapid and perfect. The diagnosis of local disease, however, must be certain before any operation is attempted, for, obviously, any operation on the sacro-iliac joint will be of no avail if there be lumbar spondylitis present at the same time. In children we have rarely found sacro-iliac tuberculosis without an associated tuberculosis at the lumbo-sacral junction.

Mechanical treatment should consist in rest in the horizontal position, and immobilization of the part by an effective brace. Only in this way can the superincumbent weight be removed and the part kept at rest. Traction in bed is useless, except in so far as it immobilizes by anchoring the limb to the bed, and traction by a walking splint is worse than useless. Indeed, the opposite of traction, namely, crowding together the joint surfaces by a broad girdle has been found to relieve the pain in cases where the suffering was increased by traction. The use of the compression girdle, combined with a spinal brace, has, in the hands of Dr. Benjamin Lee, of Philadelphia, been found to be a very satisfactory treatment.

Treatment by the "physiological" method of Hutchinson, by crutches and high patten on the unaffected side, is useful only in removing the superincumbent weight, and at best is only a palliative measure.

The most effective, and at the same time the most convenient and inexpensive apparatus for immobilizing while the patient is kept recumbent, is a modified double antero-posterior leverage hip-splint. A detailed description of the double hip-splint will be found under "Hip Disease" in this volume. The modification consists in adding a lateral wing to the main stem on each side, midway between the chest and thigh bands, and stretching a broad sling of strong leather from one main stem to the other, for the sacrum and posterior borders of the ilii to rest upon. The splint may extend to the middle of the leg, but is more comfortable, and usually sufficiently effective, if not carried below the flexure of the knees. *John Ridlon.*

SAINT-ALBAN. A spa in the department of Loire, France.

Location.—Saint-Alban is a village pleasantly situated on the left bank of the river Loire. Its cold alkaline chalybeate springs have made it quite popular as a watering place in recent years. Although the waters are largely exported, the place has not yet acquired much reputation outside of France. The season extends from June to September. The climate is mild and agreeable.

Access.—By the Paris, Lyons, and Mediterranean Railroad viâ Nevers to Roanne: thence by stage in one hour to the spa.

Analysis.—The composition of the four springs is quite similar. According to Lefort one thousand grammes of water contain:

	Source du Puits de César. Grammes.
Carbonic acid, free	1.9499
Bicarbonate of soda	0.8561
Bicarbonate of potash	0.0834
Bicarbonate of lime	0.9382
Bicarbonate of magnesia	0.4577
Bicarbonate of iron	0.0233
Chloride of sodium	0.0301
Silica	0.0451
Total	4.3838

Traces of iodide of sodium, arseniate of soda, and organic matter.

The other springs are the *Puits d'Antonin*, *Puits de Faustine*, and *Puits Neuf*. All the waters are clear and sparkling, and of agreeable taste. They are credited with diuretic, tonic, and stimulating properties.

Indications.—According to Vintras ("Mineral Waters of France") the therapeutical applications of Saint-Alban water are the same as those of Couzan. They will therefore be prescribed in the different varieties of dyspepsia, and chiefly in that which results from atony of the digestive organs; in the gastralgia which so often accompanies chlorosis and anæmia; in subacute nephritis and catarrhs of the bladder, and in chronic affections of the uterus. Inhalations of carbonic acid have been successfully used in cases of spasmodic asthma, chronic pharyngitis, and aphony.

The employment of carbonic-acid gas as an internal and external remedial agent gives an immense advantage to this station, and has, in fact, created for it a sort of specialty. Patients are no longer obliged to go to Germany to obtain this kind of treatment, but can find at Saint-Alban carbonic-acid baths, douches, and inhalations; and both the apparatus and all the details of the treatment are more complete and better organized than can be found anywhere else in France.

Accommodation.—The thermal establishment is modern in all its appliances, the usual douches, sprays, and inhalations being provided for. The lodging-houses are, however, on a primitive scale, and neither as comfortable nor as cleanly as they might be. Spacious hotels have not yet been erected. Pleasant excursions into the surrounding country are among the attractions of this place. *Edmund C. Wendt.*

SALICYLAMIDE. A compound prepared from salicylic acid by the introduction of the amidogen radical. Its chemical formula is $C_6H_4,OH,CONH_2$. The benefit of the combined action of this stimulating radical has already been demonstrated in chloralamide, and the same advantage is looked for in salicylamide, by overcoming the depressing effects of salicylic acid. It may be prepared by the action of concentrated ammonia upon oil of

wintergreen. When these stand in contact for some days in the cold, the liquid assumes a deep reddish-brown color, and brownish crystals begin to separate; impurities are removed by recrystallization and treatment with animal charcoal. It is also obtained by heating ammonium salicylate. It forms in colorless crystals and in thin transparent plates, melting at 142° C. It is soluble in alcohol, ether, chloroform, readily soluble in hot water, and in two hundred and fifty parts of cold water. It is quite tasteless and gives a somewhat gritty sensation between the teeth. After its administration it rapidly appears in the urine, and may be detected by the violet color following the addition of ferric chloride. It is excreted to a slight extent unaltered, but chiefly as salicyluric acid.

Salicylamide is proposed as a substitute for salicylic acid and its salts, the advantages claimed for it being its greater solubility, its tastelessness, and its freedom from any depressing action on the system. It also acts more promptly, and in smaller doses, as an analgesic. A very careful study of its physiological properties has been made by Dr. A. B. Nesbitt, of Toronto (*Therapeutic Gazette*, October, 1891). He sums up the result as follows: 1. Pharmacologically, it prevents conduction in nerve; paralyzes nerve first, then muscle. 2. On the heart, its chief effect being on motor apparatus, most probably through its activity on conduction. 3. Diminishes spinal reflex for motor impulses. 4. Diminishes spinal conductivity for painful impressions. 5. Diminishes muscular irritability. 6. In mammals, no particular effect on respiration. 7. No particular effect on blood-pressure. In medicinal doses reduces temperature, causes ataxic gait and hebetude in fowls.

It is employed for all conditions in which the salicylates are indicated, its beneficial effects being most marked in painful affections, as in neuralgia, ovarian pain, and chronic rheumatism. The dose advised is about fifteen grains daily, in divided doses of three to five grains. As an antipyretic, it requires to be given in fifteen-grain doses, repeated if necessary. *Beaumont Small.*

SALICYL-SULPHONIC ACID. Is now employed as a very delicate test for the presence of albumin in the urine. It occurs as a white crystalline body, very soluble in water and alcohol. It is formed by the action of sulphuric anhydride on salicylic acid, also by heating salicylic acid with concentrated sulphuric acid. Its formula is C_6H_3 (OH) (SO_3H) COOH.

This compound was recommended as a test for albumin by G. Roch (*Pharm. Centralblatt*, September, 1889) and by Dr. John A. Macwilliam (*British Medical Journal*, April 18, 1891), working independently of each other. It acts upon all forms of proteid bodies: (1) Native albumins (egg albumin and serum albumin); (2) derived albumin (acid and alkali albumins); (3) globulins; (4) fibrin; (5) albumoses; (6) peptones. In the case of all these substances a dense, bulky white precipitate is formed. When the proteid present is a native albumin, a derived albumin, a globulin, or fibrin, the precipitate is not dissolved upon boiling, but becomes decidedly flocculent. When the proteid is an albumose or peptone, the precipitate dissolves upon heating, to reappear on the cooling of the fluid. The peptone and albumose may be distinguished by saturating the solution with ammonium sulphate; the albumose is at once precipitated, while the peptone remains in solution. The peptone may then be detected by adding the salicyl-sulphonic test.

Compared with other tests, it acts either as an extremely delicate test or one less so, according as a cloudiness immediately (two or three seconds) appears, or follows after one-half or one minute. In the latter case it is one of the most delicate tests we possess, detecting 1 part of albumin in 12,500 of water; in the former, it is placed by Dr. Macwilliam between the cold nitric acid test and the acetic acid and heat test.

Dr. Roch recommended that a few crystals of the acid should be shaken with the urine, or that five cubic centimetres of a twenty per cent. solution should be added to ten cubic centimetres of the urine to be tested. Dr. Macwilliam is more exact in his manipulations. He recommends that a small amount of urine, about twenty minims, be placed in a small test-tube, and that to this a drop or two of a *saturated* aqueous solution of the reagent be added. The urine must not be alkaline, and, if necessary, should be acidulated. On adding the reagent the tube should be shaken quickly, to mix the contents, and the fluid should be examined at once. The occurrence of an opalescence or cloudiness immediately or within a few seconds, indicates the presence of proteids. The development of the reaction after an interval of a minute or two shows the presence of proteids in minute quantities, which are probably insignificant from a clinical point of view. The fluid is then to be heated, when the ordinary albumin is coagulated and formed into a flocculent mass. *Beaumont Small.*

SALIPYRIN. This compound is due to the chemical union of antipyrine with salicylic acid. It is a definite salt containing 57.7 parts of antipyrine and 42.3 parts of salicylic acid. It is prepared by the interaction of the two at a temperature of 100° C., or by adding to a boiling aqueous solution of antipyrine a proper molecular proportion of the acid. It forms as a white, coarsely crystalline powder, odorless, with a not unpleasant sweetish taste. It is almost insoluble in water, about one part in two hundred, sparingly soluble in ether, but readily soluble in alcohol. It is decomposed by acids and alkalies.

It possesses antipyretic and antirheumatic properties, and the advantage claimed for it is its harmlessness. It was introduced as a remedy for rheumatic troubles and has been used with much success in acute rheumatism, but in the chronic form it has not proved reliable. It is probably equally as serviceable as salicylic acid or antipyrine, but is equally inefficient in preventing relapses, and does not seem to offer any special advantage over other remedies for rheumatism. The amount to be given is one drachm and a half, in divided doses, during the day; the first dose being thirty grains and the subsequent doses about fifteen grains each.

As an antipyretic it is not very satisfactory; it requires to be given in doses of thirty grains, to be repeated every hour if necessary. It has been found to have its best effect when the temperature is very high; the nearer the temperature is to the normal the less noticeable is its action. Normal temperature is not influenced to any extent. It has been used very extensively in influenza, with very satisfactory results, the pains in the head and fever being relieved. As an analgesic it has proved of value in sciatica, the pains of myelitis, neuralgia, and in nervous disease accompanied by pain. Salipyrin has no direct effect on the heart, the pulse and respiration remaining unchanged, but sweating is frequently produced, and heart-burn and flatulency are of common occurrence. The drug can be detected in the urine in a very short time, but it has not any diuretic action, nor is the color affected in any way.

The results of its employment show it to be a harmless and useful drug, but not very reliable. It probably will not supersede either of its component parts.

Beaumont Small.

SALOL. (Phenyl salicylate. $C_6H_4OHCOOC_6H_5$.) The original mode of preparing salol was by causing molecular proportions of salicylate of soda and sodium-phenol to react, by prolonged heating, in the presence of phosphoric oxychloride. The reaction is as follows: $2C_6H_5ONa + 2C_6H_4OHCOONa + POCl_3 = 3NaCl + NaPO_3 + 2C_6H_4OHCOOC_6H_5$. The product is washed till free from the chloride and phosphite, and finally crystallized from alcohol. More recently a simpler method has been patented which consists in heating salicylic acid without access of air to 240° C. Under this condition the salicylic acid is decomposed and salol formed, water and carbon dioxide being separated. The change is explained in two ways. The phenol resulting from the decomposition of a molecule of the acid may, at the moment of its libera-

tion, react with another molecule of the acid so as to form phenyl-salicylate and water; or, the change may consist in the formation in the first instance of salicylic anhydride by separation of water; and, at a later stage, this is transformed into salol with the evolution of carbon dioxide.

The presence of free acids may be detected by blue litmus paper, and phenol or salicylic acid by the action of an alcoholic solution with three times the volume of water, to which a drop or two of ferric chloride has been added; a permanent violet color is produced if these impurities be present.

Since its introduction in 1886, the continuous and widespread use has confirmed the valuable properties claimed for it, and has placed it among the most important of the new drugs. Its toxic action is slight, and in ordinary medicinal use there has been but little record of unfavorable results. Its decomposition in the duodenum into its two constituents, and its excretion with the urine as salicyluric acid and phenol compounds, has been clearly demonstrated, and it is the rapidity of its course throughout the system and its free escape that render it safe and devoid of dangerous effects. When the function of the kidney is impeded, or when the drug is given in excessive quantities, poisonous symptoms may be produced. It is also advisable that a free action of the bowels should be maintained, as it has been found that when the bowels are sluggish and constipation exists, the absorption is slow and prolonged and a cumulative action is induced. When poisonous symptoms arise they are such as are referable to the phenol compounds, viz., nausea, vertigo, somnolence, weakness of the limbs, and at times irritation of the digestive tract. Salol is detected in the urine within thirty minutes of its administration, and advantage has been taken of this rapid excretion to diagnose occlusion of the pyloric orifice and motor inactivity of the walls of the stomach. In a number of cases where the outlet of the stomach was obstructed, the salol failed to appear in the urine, or was greatly delayed; and in dilatation of the organ, or where the activity of the walls was diminished, its appearance was also delayed.

The decomposition into salicylic acid and phenol in the intestines is the most important property of this drug, and has led to its employment in a vast number of intestinal disorders with decided success. Wherever intestinal antisepsis is desired it may be used with benefit. In chronic and acute intestinal disorders accompanied by fermentation, flatulence, and offensive stools, whether there be inflammatory action or not, it will rapidly check the putrefactive changes, render the stools less offensive, and reduce their frequency. In the summer complaints of children it has proved very efficacious, as much as two or three grains being given to children under one year of age, and repeated two or three times a day, or even every hour when urgency was indicated. In dysentery and other troubles of the large intestine it has proved equally serviceable. Its antiseptic action has been directed to the forms of disease in which special bacteria are present in the intestines. In typhoid fever, in addition to its very useful action as an intestinal antiseptic, it is supposed to exert a destructive action on the bacteria and shorten the course of the disease. This specific action is not very evident, nor has it been shown that the course of the disease is in any way shortened, but its antiseptic action is of undoubted value in improving the character of the contents of the bowels and preventing numerous complications that are due to the presence of the poisonous matter. In this disease various means have been tried to counteract or prevent the putrefactive changes in the bowels; charcoal, naphthalene, naphthol, and other antiseptics have been used, but salol has replaced them all, on account of its non-irritating action, and particularly, as its beneficial action is directed solely to the intestines.

The effect of salol on the bacillus of cholera has been studied more definitely. Löwenthal has conducted a series of investigations, both on the cholera bacillus and on the effects produced when administered as a remedy for the disease. A solution of salol in pancreatic juice was found to render a culture of the bacillus sterile in twenty-four hours, and in animals the administration of salol proved a protective against inoculation. As a remedy for cholera it is given in thirty-grain doses, to be followed by fifteen grains every half-hour or hour. It has been used to a great extent, and reports of the results obtained are very favorable. Dr. Francisco Gonzalez, in the Philippine Islands, where cholera is endemic, reports its use in fifty-three cases with only six deaths. Dr. Nicholson, of Patna, India, employed it in eighteen cases, in all of which recovery took place, although eleven were in a state of collapse when treatment was begun; and Hehir reports eleven cases treated, with no deaths. In all intestinal disorders the drug is best administered with an alkali, as bismuth, bicarbonate of sodium, or chalk mixture; the salicylate of bismuth or the salicylate of magnesium may also be used and adds to the antiseptic action. Naphthol has also been combined with it. The dose usually employed is eight or ten grains every three or four hours, until it produces its effect, and then it is given in smaller doses to maintain antisepsis. It may be given in powder in sachets, or in emulsion, in oil, or in mucilage.

The rapid excretion of salol by the kidneys in the form of salicyluric acid and compounds of phenol, renders it of great value as a remedy in various disorders of the genito-urinary organs. The property of rendering urine aseptic is of the greatest practical importance, and is taken advantage of in all forms of chronic inflammation of the bladder, in which the urine is alkaline and loaded with mucus. It renders the urine acid, the sediment rapidly disappears, and the condition of the diseased mucous membrane is improved. It has been found of great service in such cases in combination with vesical irrigation. When febrile reaction follows the introduction of the catheter or sound, its use for a few days is found to prevent this change, and its administration for a week previous to the operation of litholapaxy, enabled a patient, who previously was subject to a chill upon the slightest examination of the bladder, to undergo the operation without the occurrence of any unpleasant after-effect. It has proved of service in gonorrhœal inflammation, and has recently been advocated as a remedy in catarrhal states of all mucous membranes, as the pharynx, larynx, bronchial tubes. In all the conditions in which its excretion from the system is utilized, its beneficial action is increased by combining with it terpin hydrate, copaiba, or oil of sandal wood, in all of which it is readily soluble to the extent of one-third of their weight. Ten grains three times a day, have been found sufficient to secure its action in these cases, and this may be given in all periods of the inflammation without causing any unfavorable action, although it is in chronic inflammation that it proves most serviceable.

Salol has been used in the treatment of rheumatism, and was thought to be a remedy that would prove of decided value. The results have not been equal to what was expected, and such use is secondary to its employment in the other diseases mentioned. In many instances it has been used with benefit, but it is not equal to the salicylates and other anti-rheumatic remedies. For this purpose it is given in doses of fifteen and twenty grains, the aggregate during the twenty-four hours being from four scruples to two drachms.

It has recently been recommended in the treatment of diabetes. In doses of thirty grains it was found that the glycosuria is lessened or caused to disappear, and the amount of urea diminished. It should be used in cases in which the diet is carefully regulated, and in which there is no albuminuria or nephritis.

Externally, salol is used as an antiseptic and deodorant in the treatment of wounds, ulcers, suppurating surfaces, parasitic skin diseases, and all conditions in which iodoform and other antiseptics prove of value. As a powder it is mixed with equal parts of starch, or French chalk, or boric acid. It may be used in collodion, four parts to four of ether and thirty of collodion; or in the form of five to ten per cent. alcoholic solutions. The latter may be diluted with water for gargling or for local applications. *Beaumont Small.*

SALOL - CAMPHOR. These two substances, when mixed in certain proportions, alter their physical state and become an oily, colorless liquid, insoluble in water, freely soluble in ether, chloroform, and oils. It is prepared by adding twenty parts, by weight, of powdered camphor to thirty parts of salol, and warming gently until fusion is complete, without adding either alcohol or water. It should be filtered and preserved in a green glass bottle, well closed, as under the influence of air and light it is readily decomposed.

It possesses the properties of its constituents, and is highly recommended as a stimulating antiseptic. It is used especially for the treatment of suppurative otitis of the middle ear. The manner of employing it is to cleanse the external auditory canal and tympanum, and then introduce into the ear a small pledget of absorbent cotton impregnated with the camphorated salol. This should not be allowed to remain more than twelve or twenty-four hours. During the intervals the ear should be well syringed with a warm solution of boric acid. The treatment should be continued for some weeks, and is said to produce a cure in many cases. The application is neither painful nor irritating, and almost invariably exercises its antiseptic and disinfectant action. *Beaumont Small.*

SALOPHEN. (Acetyl-para-amido-salol.) A patented compound which is, chemically, salol in which one atom of hydrogen in the phenyl group is replaced by the monivalent group $NHCOCH_3$. It occurs in minute, white, crystalline plates, insoluble in cold water, very slightly soluble in hot water, soluble in alcohol and ether. Alkalies render it soluble, even in cold water. It is without taste or odor, and is neutral in reaction. Salicylic acid is present to the extent of fifty-one per cent. The acid secretion of the stomach has no effect upon it, but when it comes in contact with the pancreatic ferments it is decomposed into salicylic acid and acetyl-para-amidophenol. The object in view in the production of this compound was to improve upon salol by combining with the salicylic acid a phenol compound which was perfectly harmless. This, however, causes a great difference in the therapeutic properties, and it is solely to the salicylic acid that salophen owes its medicinal action, the phenol compound not being absorbed and having very little, if any, effect upon the system.

It is recommended as a remedy for acute articular rheumatism in doses of sixty to seventy-five grains during the day, the usual dose being fifteen grains every three or four hours. Several reports of its employment have been published, in all of which it appears to have proved satisfactory. The pain and swelling are rapidly relieved, and the temperature reduced to normal in two or three days. It does not disagree with the stomach nor produce any toxic symptoms. Relapses, however, take place and the ordinary complications are not prevented. In chronic rheumatism it has been used without affording any marked relief or improvement. It is suggested as an intestinal antiseptic in diarrhœa, typhoid fever, and cholera, but no cases have yet been reported in which it has been used.

Upon the urine it has little action, and has not been found to be of any benefit in urinary disorders.

Beaumont Small.

SALZBRUNN. A popular spa in Silesia, Germany.

LOCATION.—Salzbrunn is a village pleasantly situated in the wooded district of Breslau, at an elevation of twelve hundred and fifty feet above the level of the sea. Its mineral springs enjoy considerable reputation in the treatment of a variety of diseases. The place is midway between Waldenburg and Freiburg. Season, May to October.

ACCESS.—Salzbruun is a railroad station on the Breslau-Freiburg branch line.

ANALYSIS.—The principal spring is the *Oberbrunn*, but there are quite a number of other springs, such as the *Wiesenbrunnen*, *Sonnenbrunnen*, and *Heilbrunnen*, the waters of which are employed for baths, douches, etc. The *Kronenquelle* (private property) is also a favorite spring. Salzbrunn is often alluded to as the *cold Ems*, although the composition of its mineral springs is by no means identical with that of the Ems water. One quart of Salzbrunn water contains (average analysis):

	Grains.
Sodium bicarbonate	26.00
Bicarbonate of lime	7.20
Bicarbonate of magnesia	7.60
Bicarbonate of protoxide of iron	0.004
Sodium chloride	2.60
Sodium sulphate	9.40

There is also a large proportion of free carbonic-acid gas.

INDICATIONS.—Salzbrunn is chiefly visited by patients with catarrhal troubles of the respiratory organs, including phthisis. But invalids with gouty and rheumatic affections, nervous disturbances, diseases of the bladder and kidneys, also frequent this spa. There are facilities on a large scale for milk- and whey-cures, and the thermal establishments are modern and complete in every detail.

ACCOMMODATION.—The hotels and lodging-houses are good. The authorities provide the usual amusements of spa life. There are good opportunities for interesting walks and excursions. The place is semi-fashionable, and prices are therefore moderately high.

Edmund C. Wendt.

SANITARY INSPECTION. 1. DAIRY-FARMS, DAIRIES, AND MILK SHOPS.—Cow's milk has been denominated a model food, because it is perfectly adapted to the needs of the human economy. Its use is universal. It often constitutes the sole food of infants and sick persons, and enters very generally into the diet of most individuals. It is therefore of the utmost importance that its purity be maintained.

The sanitary and economic advantages of milk inspection cannot he over-estimated. Injury to health which results from the use of adulterated or impure milk is due to deficient nutritive value or to contamination by the specific contagium of such diseases as scarlet fever, typhoid fever, diphtheria, tuberculosis, possibly of anthrax or malignant pustule, and foot-and-mouth disease, or to some abnormal condition imparted to it by the cow, or arising after the milk has been taken from the gland. Milk may he poisoned by the animals feeding on improper food or hy improper management. Tyrotoxicon, an organic poison, is sometimes developed under the latter circumstance, its effect upon the young infant being very serious.

As commonly practised, adulteration consists either in the addition of water, or in the removal of more or less of the cream, or both. The effect of lowering the nutritive value of an article that enters so largely into human diet, that is so much depended on in the sick-room, and that is so universally used as food for infants, can be readily comprehended. The pecuniary loss suffered by the purchasers of adulterated milk, though a lesser consideration, is a feature of the question which concerns the public in no slight degree.

In order to insure the purity of milk it is necessary to enlarge the scope of milk inspection as commonly practised. The law directs that only pure milk shall be sold, and yet the means of accomplishing this object fail in some most important particulars. Milk may be the vehicle of conveying the poison of disease. It has been proved beyond doubt that the materies morbi of enteric fever, of scarlet fever, and of diphtheria has been conveyed through this medium, and it is extremely probable that tuberculosis can be transmitted in the same way. The tests ordinarily applied to milk fail to detect the specific germs of these diseases.

Chemical analysis, though of the greatest advantage in determining the composition of milk, and in detecting adulteration, is unable to discover the living pathogenic entities, which are the more dangerous because of their power of directly producing disease. In order, therefore, to guard against this subtle danger, and to render

milk inspection a positive protection, it is necessary to resort to other methods of investigation. Fortunately, in biologic examination we have a valuable means of supplementing chemical analysis. If biologic examination were only occasionally the means of detecting the tubercle bacillus in milk, the discovery would be of sufficient value to compensate for the investigation, for by it the dairy-farm where the milk was obtained could easily be discovered, and the diseased animals that day after day caused the milk of the entire herd to be infected could be promptly destroyed.

But the investigation need not be confined to tuberculosis. Biologic science has made rapid strides, and is constantly adding to our knowledge of the rôle played by micro-organisms in the causation of disease. This knowledge, whenever practicable, should be made use of in conserving the public health. Both chemical analysis and biologic examination have their special and well-defined fields of exploration. When one fails the other may be able to make valuable discoveries. Their office is to aid one another and to supply each other's deficiencies. Hence, the best results are to be obtained when the two methods of examination are combined.

Another means of protection, and a most important one, because it strikes at the source of contamination, is the systematic inspection of dairy-farms, dairies, and milk shops. It is to this part of the subject that special attention is directed, as provision is seldom made for such inspection. This practice is required by the English law, and to some extent is carried out, but in America it is almost entirely neglected.

Milk may be contaminated by the addition of impure water in the milk-houses, and is frequently adulterated after it leaves the dairy-farm; but the most dangerous source of contamination is at the dairy-farm itself. For this reason inspection is very incomplete that does not include a watchful supervision of the cattle, their environment and treatment, and all the conditions under which the milk is prepared for the market. The seeds of tuberculosis lie concealed in what to all appearances is wholesome milk, and who can tell what amount of disease is distributed through the unsuspected agency of this common article of food? There is less likelihood of infection from anthrax or malignant pustule, and foot-and-mouth disease, as self-interest prompts the dairyman to quickly exclude from his herd animals sick with these diseases.

It has not been determined whether or not the milk of cows suffering from actinomycosis, caused by malignant ray-fungus, is capable, through its ingestion, of propagating disease, but until this point is decided, milk from cows suffering from this affection should be rejected as suspicious. Mr. Ernest Hart has tabulated a number of epidemics of enteric fever, scarlet fever, and diphtheria that have been definitely traced to milk infected at the dairy-farm. The milk of cows fed on distillery swill, or that are sickly, or in bad condition from unsuitable food, impure water, bad housing and care, or that have recently calved, or that have become exhausted from any cause, cannot be regarded otherwise than with suspicion. Milk is known to have been infected by the hands of the milker convalescent from scarlet fever. Typhoid fever has been propagated by the use of infected water for rinsing the milk cans and diluting the milk.

It is seen that the liability to contamination to which milk is exposed at the place of collection is very great, and constitutes the chief source of danger, especially so, as most of the elements of danger may escape detection by the ordinary methods of laboratory investigation. Hence the necessity of establishing systematic inspection of all dairy-farms, as well as of milk shops, by competent officers amply clothed with authority to compel the observance of regulations for their proper sanitary administration.

It is important that none but healthy cattle should be permitted in the herd. Cows affected with tuberculosis, or other dangerous infectious or contagious diseases, should at once be isolated or destroyed. In order to detect these diseases, especially in the prodromal stage, it is necessary to make use of the knowledge of the expert veterinarian. The farmer cannot be expected to possess the knowledge and tact required to make a reliable diagnosis. Until the diagnostic value of tuberculin was discovered, even the skilled veterinarian frequently failed to detect the disease when not in its advanced stages. To this difficulty of diagnosis and the lack of proper inspection, may be attributed the prevalence of the disease. If it could have been more easily detected in living animals, it is safe to say that the attempts made by the owners of cattle to eradicate it from their herds would have been more successful.

Only healthy cattle can be expected to produce wholesome milk. Hence, the environment, care, and feeding of the stock should be studied with the view of obtaining the best hygienic results. Pure water is quite as essential to the health of cattle as is wholesome food. Special attention should be directed to the housing of the cattle. Cleanliness, light, and ventilation are most important requirements. The drainage should receive the strictest examination. Dampness is especially to be avoided. The greatest cleanliness is to be observed in handling and storing the milk. The possibility of contamination of the water-supply from any source, especially by the cesspool, is to be guarded against. The proper cooling of the milk is a precaution the value of which the dairyman should fully understand.

Should contagious disease break out in the dairyman's family, he should be prepared by previous instruction to guard the milk-supply from this source of danger. Printed instructions, covering the management of the dairy-farm, should be supplied to the farmer, and the inspections should be sufficiently frequent to see that the instructions are faithfully carried out. By adopting the plan thus briefly outlined, in conjunction with inspection performed in the city, supplemented by the tests made in the laboratory, there is the assurance that the milk-supply will be most effectively guarded against adulteration and contamination.

Cities obtain their milk-supply from surrounding and even distant counties, it may be from neighboring States, from territory lying beyond their jurisdiction, and they are, therefore, powerless to exercise for their own protection the necessary supervision at the source of supply. This is also true to some extent of towns and villages, though in the case of these there is less difficulty in gaining knowledge of the conditions under which the milk is procured for the market. In order, therefore, to bring about the desired results, inspection of dairy-farms and dairies should be conducted under the provisions of a law applying to the whole State.

The eradication of infectious disease from among cattle benefits the farmer, both directly and indirectly, and at the same time protects the consumer of milk against disease liable to be communicated through this medium. This is one of the objects accomplished by a comprehensive system of sanitary inspection and management of dairy-farms, dairies, and milk shops, which aims to prevent the dangers connected with the milk-supply. In the absence of a general law, individual communities can protect themselves by not permitting the sale of milk except under license granted to those producers only who are willing to submit to inspection of their herds and farms by qualified persons, at such stated periods of time as may be determined upon, the license to be valid only so long as the results of such investigation are shown to be satisfactory. The feasibility of this plan is foreshadowed by the fact that some producers, from self-interest, have put into practice a system of periodic inspection of their farms, and of certification of the health of the stock and the sanitary condition of the surroundings. The value of such inspection depends upon the impartiality and reliability of the person conducting it, and is apt to be impaired by prejudice in favor of the interests of the employer. Uncertainty of result is avoided by placing the inspection service under the absolute control of the civic authorities. The voluntary adoption of the plan of inspection is a recognition of the fact that a public sentiment exists in favor of more stringent meas-

ures of protection against dangers in our milk-supply, and, therefore, deserves to be encouraged.

2. Contagious and Infectious Diseases. — The prompt recognition of the first cases of contagious or infectious disease is of the greatest importance, as upon it will often depend the possibility of preventing its spread. It is important not only that these cases be early recognized, but when recognized that they be immediately reported to the local health authority, in order that measures be employed to prevent the scattering of seeds of contagion. Prompt notification is a step so necessary to the precautionary supervision of contagious and infectious diseases, that in communities where good sanitary organization exists it is made obligatory by penal statute. Whether the obligation to report such cases be placed upon the physician or upon the head of the family, is a matter of secondary importance.

The object of prompt notification is to enable the sanitary authorities at the very outbreak of the disease to inquire into all the circumstances of the case, to cooperate with the medical attendant in his efforts to prevent the spread of contagion, and when necessary, to resort to such measures to protect the public health as it is the prerogative of these authorities alone to enforce.

Whenever it comes to the knowledge of the local health authorities that a case of dangerous contagious or infectious disease exists, it is their duty to at once cause a thorough inquiry to be made into all the particulars of the case by a sanitary inspector qualified for the responsible duty by experience and sound medical training. The inspector should consult the medical attendant and satisfy himself as to the true nature of the disease, learn its origin and history, and acquaint himself with the surroundings, the plan of isolation adopted, and the other measures employed to prevent the spread of the disease. He should determine upon this examination whether the patient can be properly and safely cared for at home, with respect to the patient himself, the occupants of the house, and the public. If from poverty or inadequate facilities for managing the case, or the impossibility of isolating the sick person, or for any sufficient cause, this cannot be done, it is his duty to at once recommend the removal of the patient to a hospital for the treatment of such diseases. After removal of the patient, which the authorities should be empowered to direct, prompt and thorough disinfection and other precautionary measures should be carried out under the direct supervision of the inspector. The household should thereafter be kept under close observation until the period of incubation of the disease, dating from the latest exposure to contagion, has passed.

On the other hand, when the inspector finds that every necessary measure of precaution is being faithfully carried out, and that the sanitary management is satisfactory, he will report the fact and keep the case under observation. Between these two classes of cases there are those not so easily disposed of, in which the course of action to be pursued will have to be determined by the best judgment of the inspector according to the circumstances.

Printed instructions, explaining in plain language the nature of the disease, its mode of propagation, the means of isolation and disinfection, and all the precautionary measures necessary to observe from the beginning to the end of the disease, and thereafter, should be left with the family of the sick in every case, and explained when necessary.

The duties of the inspector are delicate as well as responsible. He has nothing whatever to do with the medical treatment of the patient, and comment thereon, especially before the family, is out of place. He should respect the rights of the medical attendant and should endeavor, as far as possible, to make his visits at the time when the physician is expected to be present. While nothing necessary to be known should escape observation, he should be careful not to excite opposition by inquiring into matters that do not strictly pertain to the object of his mission. By tact and politeness it is possible in nearly all instances to obtain the co-operation desired. When, however, through ignorance or prejudice, or for whatever reason, the instructions of the inspector are disregarded and measures of precaution are ignored, steps should at once be taken to compel obedience.

The sick should be isolated either at home or by admission to a special hospital. Every community should provide a hospital for contagious diseases, and when possible each disease should be treated in a separate pavilion. In locating such a hospital convenience of access should be a prime consideration. In transferring a patient it is not permissible to use a public conveyance, but an ambulance so constructed and equipped as to insure comfortable and safe transportation. Disinfection of the ambulance after each time it has been used should not be neglected. Every effort should be made to overcome the prejudice against removal to a public hospital which so commonly exists. If the transportation, accommodation, care, and treatment of the patient be without fault and the expense nominal, opposition to removal will be reduced to its lowest point. It is detrimental to the patient and to the service to resort to compulsion, yet there are circumstances which fully justify it.

It is advisable to remove the well persons in the family from the house when practicable, if there is reason to suppose that they have not become infected. Intercourse with the house should be restricted or prohibited altogether, according to circumstances. The inmates are not to visit or to attend public gatherings, and children of the family are to be prohibited from attending school until all danger of communicating the disease has passed. Isolation of the sick at home is practically seldom perfect, and it is therefore prudent to act upon this assumption. Inspection should be sufficiently frequent to determine whether these rules are observed. When there is reason to mistrust compliance, there is the alternative of removing the patient or of placing a watchman on duty to compel obedience to the law.

The sanitary inspector should satisfy himself that all the details in the preventive management of the case are being strictly carried out under the direct supervision of the medical attendant. When he is not thus satisfied, it is his duty to interfere to the extent of personally directing the necessary measures to be observed. Isolation of the sick person, thorough cleanliness, ventilation, disinfection of the discharges, and of everything before it leaves the sick-room, must be insisted upon. Printed directions as to the various observances, to be left with the family for reference, will be of the greatest assistance to them in comprehending what is required to be done.

As it is often practically impossible to properly disinfect at home some articles used in the sick-room, it is necessary that every community should provide a public disinfecting plant to supply this deficiency. Steam-disinfecting chambers, constructed preferably of steel, in which articles can be disinfected by dry or moist heat at a given temperature, are indispensable in the management of contagious or infectious diseases. Their use should be offered to the poor gratuitously, and to those able to pay at a nominal charge.

While the sanitary inspector should have knowledge of the principles and practice of disinfection, so as to be capable of giving instruction, it is not expected that he shall personally do the work. The health department of a city is not deemed fully equipped unless it includes in its personnel one or more disinfectors. "The object of disinfection is to prevent the extension of infectious diseases by destroying the specific infectious material which gives rise to them. This is accomplished by the use of disinfectants. There can be no partial disinfection of such material—either its infecting power is destroyed, or it is not. In the latter case there is a failure to disinfect." On account of the great importance of having this work properly performed, it is necessary to intrust it to persons specially qualified by knowledge and experience. The disinfectors should be under the direction and control of the sanitary inspectors, who should be held responsible for the faithful performance of the work.

It is not intended that the disinfector shall obtrude his presence in the sick-room during its occupancy by the

patient, as the medical attendant can supervise the necessary measures there required. But after the termination of the sickness it is his duty to personally take charge of disinfection of the sick-room and the premises, to superintend the removal of such articles as are required to be taken to the public disinfecting chamber, and to see that all the details of the work are properly carried out. He is to supply the necessary apparatus and materials when needed.

Careful discrimination is required on the part of the sanitary inspector in regard to the cases coming under his observation. It is only when he is satisfied that the work cannot be properly performed without his intervention, that he is justified in employing the services of the disinfector.

It is the duty of the sanitary inspector to follow each case to its termination. In the event of death he is to see that all regulations governing such cases are strictly observed, especially that no public funeral takes place. In any event, he should satisfy himself that every necessary measure of precaution is fully carried out.

There is a difference of opinion as to the advisability of placarding houses in which contagious or infectious diseases exist. There are benefits to be derived from warning the public of danger; but, on the other hand, the common aversion to the requirement may lead to the suppression of the true knowledge of the disease, which may be attended with disastrous consequences. Under a well-organized system of sanitary inspection this practice might be dispensed with.

Small-pox is prevented by vaccination. When a person is stricken with this disease the greatest diligence should be exercised in tracing its origin, in locating all persons and things that may have been exposed to the contagion, and in making use of the means necessary for arresting the spread of the disease. All unprotected persons should be promptly vaccinated, in order to prevent the disease or modify its character. Persons exposed to the contagion, although previously vaccinated, should, for the sake of prudence, have the operation repeated, unless the evidence of protection is undoubted. An epidemic may be prevented by the early recognition of the first cases, and the prompt application of the means of restriction.

The utmost vigilance is required when cholera threatens a community. Lest the true nature of the disease be overlooked on account of the similarity of the early symptoms of Asiatic cholera and cholera morbus, it is prudent to regard all cases of severe choleraic diarrhœa as suspicious, and to hold them under strict observation until a positive diagnosis is made by means of the results of a biological examination of the discharges. As it will take from twenty-four to forty-eight hours to make this test, during this time, and while there is a doubt as to the true nature of the disease, the case should be carefully watched, and the precautionary measures necessary in the management of Asiatic cholera strictly carried out. When cholera is impending, every physician called to a case at all suspicious, stands in a position of great responsibility, not only to the patient, but to the public. He should be wary, therefore, that no remissness be charged against him. He should report promptly his suspicions to the health authorities and offer them his full co-operation.

When a case of Asiatic cholera occurs it should be placed under constant sanitary surveillance, and every avenue by which the disease might be spread carefully guarded until all danger has passed. What is possible to be done at the very introduction of the disease, becomes a discouraging and formidable undertaking when once it has assumed an epidemic form. Hence the utmost vigilance should be used with regard to all first cases, and everything should be done to prevent them from becoming foci of contagion.

Accurate records should be kept of all cases of contagious and infectious diseases reported. These records should show the name, age, sex, color, and residence of the sick, the disease and its termination, and such other data as may be of value.

3. Railroads, Cars, Stations, Passengers, Etc.—The object of such inspection is to ascertain whether all necessary measures of precaution are practised to protect the health of the travelling public; and further, whether measures are formulated and understood, and are ready for instant application, to prevent the spread of contagion either occasionally introduced, or which is imminent when an epidemic is impending or actually exists. The transportation of immigrants from an infected locality may spread disease at their destination or along the route, if not carefully conducted upon established sanitary principles. Contagion may lurk in cars to the injury of the unsuspecting traveller, if disinfection is not practised.

Sanitary and precautionary regulations for the government of railroads should be prescribed under State laws and administered by State boards of health. Uniformity of regulations and practice is desirable, and is best attained by concerted action of these boards in formulating and executing the necessary measures. The enforcement of these regulations is secured by sanitary inspection, which, under ordinary circumstances, should be performed periodically and at sufficiently frequent intervals to secure the object. During the prevalence of an epidemic of contagious or infectious disease, or when such is impending, it will be necessary to have a rigid inspection service established at threatened points. It may be on the frontier, at the seaboard, State lines, or at important railroad centres. Such service should be conducted under co-operation of different State authorities, with the general Government, when necessary, so as to accomplish the desired results without unnecessarily multiplying the acts of official interference and needlessly embarrassing the transportation companies and interfering with travel.

Sanitary regulations governing railroads should prescribe the precautionary and preventive measures to be carried out at all times under the direct supervision of special officers of the companies, and also such restrictive and repressive measures as become necessary during the prevalence of an epidemic of contagious disease.

Precautionary and *preventive* measures aim to secure clean air, clean water, and clean environment, and the prevention or removal of all causes that tend to their defilement. The water-supply should be of known and reliable purity of source. The utmost cleanliness should be enjoined in storing and handling it, and with regard to all receptacles. Water-coolers should be cleaned frequently under strict supervision. In the event of diseases being prevalent, such as may be communicated through the medium of drinking-water, as cholera, for example, it is imperative that the water used for drinking purposes in cars, stations, etc., should be boiled for at least half an hour. The greatest care should be observed in selecting ice of known purity, as well as in storing and handling it. Drinking glasses or cups, which are liable to communicate disease, should, under the circumstances, be subjected to frequent and thorough disinfection, supplemented by washing in clean water.

Thorough cleanliness of passenger cars, disinfection and scrubbing of floors and woodwork, and the heating and cleaning of seats, carpets, drapery, etc., and thorough cleanliness of stations in every particular, of floors, hangings, carpets, closets, cuspidors, and neighboring track spaces, are all most essential.

The cabinets and the receptacles for fecal matter should be so constructed that the most perfect cleanliness can be easily maintained. The floors and wainscoting should be made of non-absorbent material, and no cracks or corners should be left to collect matter. Enclosed spaces about the fixtures are not permissible.

The practice of discharging excreta through open tubes upon the roadway is an uncleanly one, and is further and mainly objectionable on account of the risk involved to the public health. The danger is not from healthy fecal matter, but from diseased matter which, under the present arrangement, cannot be intercepted and prevented from being scattered along the surface of the road-bed, from which it may be washed into water-

courses and specifically contaminate the supply of water used for domestic purposes.

The cabinets as well as the receptacles should be frequently disinfected, and thereafter scrubbed or washed with soap and water.

No railroad is complete in its equipment that does not possess at its terminals, or at convenient points, the appliances and means for efficient disinfection. Railroad companies are under obligation to transport the public in a safe and comfortable manner. They also have the further obligation to protect the health of travellers while in their charge. Developed cases of contagious diseases are easily discovered and disposed of, and disinfection performed according to established rules. But the subtle poison of contagion more commonly escapes detection, and lurks in the sleeping-berth, the drapery, carpets, drinking-cup, and in the excreta cast recklessly upon the roadway. Practically speaking, nothing is ever done to destroy such poison. The so-called cleansing is according to the usual custom and satisfies the senses only, but as it is not aimed to destroy the disease germs, it is deceptive, since it lacks this most important object. Even under the observance of the strictest precaution, contagious diseases may be communicated by all of these media. Without it the danger is many times multiplied. Now that it is well established that tuberculosis, that most destructive of diseases, is communicated through the expectoration of the sick person, it becomes obligatory upon the railroad companies to guard their patrons while in their charge by well-known means from hazard from this and other communicable diseases, as far as is practicable.

For the reason that the danger is constant, though it escapes ordinary attention, periodical and systematic disinfection of the carpets, matting, hangings, beds and bedding, drinking-glasses, water-closets, and woodwork should be enjoined. Cleansing, as usually practised, is insufficient. Chambers for disinfecting by moist and dry heat are now considered to be an essential part of the sanitary equipment of every railroad.

Ventilation, heating, and lighting of cars and stations, deserve consideration. There would be little difficulty in securing proper ventilation of cars during the summer season, if it were not for the constant presence of dust, smoke, and cinders in the atmosphere surrounding a moving train. With stone-ballasted roadbeds and the use of devices for consuming smoke, the objection to ventilation by the open windows or transoms vanishes. But during that portion of the year when artificial heating is necessary, no satisfactory system for supplying passengers with wholesome air warmed to an agreeable temperature has yet been introduced. Tests made to determine the amount of carbon dioxide in the air of occupied coaches in the winter season, when doors and windows are closed, show, by the mean of all analyses made, that the air contains an excessive amount of this impurity, and prove that the means of ventilation in cars is inadequate to supply a wholesome atmosphere.

In order to accomplish the proper ventilation of cars mechanical means must be resorted to. And these means should be adequate to introduce within the car, at all times, a sufficient amount of fresh air to maintain the standard of purity. When artificial warmth is required, the air should be passed over heating apparatus, and thus warm the car as well as ventilate it. Whether a system of ventilation by extraction, or by propulsion, or both methods combined, be adopted, is immaterial so far as the main object is concerned. The question of expense is a subordinate consideration.

The fact that within recent years railroad trains run over extensive routes without change of cars, and that people live upon these cars for days as in any other place of residence, makes it highly important that the sanitary conditions necessary to comfort and health should receive most careful attention.

The old plan of heating by stoves should be discarded as unsatisfactory and extremely dangerous, and in lieu thereof a system of heating by means of steam or hot-water pipes should be substituted, it being more easily regulated, more satisfactory in its results, and immeasurably safer. Coal-oil lamps are unsatisfactory, and are open to the objection that they contaminate the confined air by the products of combustion, but more particularly on account of the risk of explosion and fire. Gas burners, with ventilating flues, are preferable. The Siemens or Lungren gas burner has powerful illuminating qualities, and the further advantage of discharging the products of combustion outside the car. The incandescent electric light is the ideal hygienic light, and, barring expense, is preferable to all other means of illumination.

Every appliance that conduces to the safety and protection of the lives of passengers and crew should be promptly adopted by the railroad companies. The so-called block system of signals has frequently averted accident and thereby saved life, and should be universally introduced. Statistics show that a large number of lives are annually sacrificed by the unnecessary and persistent employment of the link and pin coupling for cars. Strange to say, there is an opposition among the men employed to the substitution of the automatic coupler for this dangerous appliance, possibly for the reason that the new invention, which is safe and well adapted to its use, requires no special dexterity, and its adoption will lead to a reduction of wages and a reduction in the number of men required to perform this work. Where life is unnecessarily jeopardized the law should intervene and make the adoption of some form of automatic coupler obligatory.

The discharge of volumes of smoke, especially from engines using bituminous coal, is a nuisance not only to travellers, but to persons living in the vicinity of railroad yards, and even along the built-up portion of the routes. It is not so much a question of health as one of comfort, but the two are intimately related. A smoky, dirty atmosphere, however, is not conducive to health. Appliances have been invented which thoroughly consume the smoke, and their adaptation to locomotive engines has been a success, and there can be no valid reason why they should not be put into general use.

Railroads are occasionally liable to transport infected persons, and therefore should be prepared at all times to deal with such cases. But during an epidemic of contagious or infectious disease the liability becomes constant, particularly along such roads as are immediately connected with the disease centres. Under such circumstances the use of *restrictive* and *repressive* measures becomes imperative. They are primarily *inspection, cleanliness, isolation,* and *disinfection*. Cleanliness in the strictest sense of the word is at no time more important. Cleanliness with regard to the water-supply, vehicles, stations, closets, etc., should be strictly observed. The precautionary and preventive measures already advised should be executed with fidelity and precision. With regard to the water-supply, the greatest safety lies in boiling all water used for drinking purposes, for which adequate provision should be made.

The inspection of passengers and cars at proper stations by skilled officers, for the purpose of detecting disease, supervising the sanitary condition of the vehicles, and disposing of the sick, is imperative. A sanitary officer should accompany every immigrant train, in order to have early knowledge of any sickness that may occur and direct the proper measures to be taken. The transportation of all suspicious cases of disease should be refused. Immigrants should be transported on special trains, but should be detained until satisfactory inspection has been made as to their health conditions. The health authorities at the place of destination should be notified in advance of the coming of such trains, and a certificate of health (issued by the proper official) should be in the possession of each immigrant. State boards of health should be promptly furnished with a list of the names and ultimate destination of persons coming from an infected district.

Arrangements should be made for treating the sick and for disinfecting cars and their contents at convenient stations, such as the inspection stations, patient-delivery stations, and at the terminals of the roads. Patient-delivery stations are such stations as are provided with a

suitable place for the reception of the sick while awaiting the means of transportation, and with accommodation in hospital. An inspection station and a delivery station may sometimes be advantageously combined.

At a number of these stations, and at stations where a considerable number of passengers arrive from an infected district, and at all important railway centres, under the direction of the sanitary authorities, physicians should always be in attendance when trains arrive, in order to render assistance to persons sick, or suspected of being sick, with the prevalent disease. They are to render assistance when requested by the sick travellers, or when information is given them by the conductors who have obtained it by their personal observation, or upon the statement of travellers.

The selection of these stations should be made by the sanitary authorities with the concurrence of the railroad officials, and with reference to the character of the epidemic and the conditions of traffic.

A list of all delivery and inspection stations should be furnished the conductor of every passenger train, and he is to deliver persons taken sick with suspicious symptoms at the next station on the list. The delivery of cholera-suspicious persons at other than the designated stations should, as a rule, be prohibited. If, however, a passenger insists upon leaving the train before such station is reached it may be permitted, unless there is a police regulation against it; but in such case the conductor should notify the officer in charge of the station, giving the name, place, and residence of the sick person, in order that the proper authorities may at once have full knowledge of all the facts.

Immediate telegraphic notice should be sent to the nearest delivery station when suspicious sickness occurs on any train. When a case, or the suspicion of a case, of cholera appears, all persons in the car, excepting friends of the sick person who wish to remain to take care of him, should be removed; and such persons, upon arrival of the train at the station, must at once be pointed out to the sanitary official in order that he may give the necessary instructions with regard to them. The sick should be made as comfortable as possible. Arriving at the station, the car should be side-tracked and placed under the direction of the sanitary officer.

Suitable rules should be prepared for the use of train officials in disinfecting themselves after having been in contact with the ejections of sick persons, and they should call the attention of travellers who have been exposed to infection to the necessity of disinfection. All persons coming in contact with cholera patients must strictly avoid eating, drinking, smoking, or bringing their hands in contact with the face before disinfection has taken place, as infection may occur by direct introduction of poisonous matter through the mouth into the body. Workmen employed to disinfect should be equally careful to disinfect themselves immediately after they have come in contact with infected things. Every confirmed case of cholera should be reported at once in writing by the station-master, to the local police authorities, and to the friends of the patient, with information as to the place whence he or she came, name, age, and business, as well as the destination.

The foregoing instructions should apply to all train officials who may be taken sick during the journey.

Disinfection of car closets should be frequent and thorough. In order to prevent infecting the roadway, and from this source neighboring streams, whereby disease may be communicated, movable iron buckets or boxes should be substituted in the place of all car closets, or some other mechanical device should be used by which excreta shall be prevented from escaping upon the road-bed without disinfection. This measure is important with respect to all trains, but it is particularly applicable to immigrant trains starting from the seaboard, when vessels are arriving from infected countries. The disposal of excrement should be under strict regulation.

The disinfection of cushions, drapery, carpets, beds, bedding, etc., by means of steam, is deemed essential when these articles have been exposed to the infection of such diseases as small-pox, cholera, etc. For this purpose steam-disinfecting chambers should be provided at the inspection stations, or some equally satisfactory arrangement be made for carrying this object into effect. The disinfection of the personal effects of the sick or of suspects is best accomplished by means of steam, and should be performed at the place where the cars are side-tracked. Cars exposed to infection should be thoroughly disinfected while at the stations, according to well-established methods. With ample provision and good management all these measures can be carried into execution with but trifling hindrance to traffic. Circulars of instruction should be in the hands of all officials of the road liable to take part in the service.

4. Steamboats, Ferryboats, Stations, Etc.—The sanitary inspection of steamboats, though less important than that of railroads, is necessary for the protection of the public health. The vast rivers and inland waters of the United States afford numerous and convenient channels of communication which are extensively utilized for passenger traffic and commercial purposes. Safety in navigating these waterways depends on knowledge of the channel and the proper construction, equipment, and management of the transports. The Government, in the exercise of its sovereign authority, seeks to prevent accidents and protect life by the enforcement of necessary regulations, such as those limiting the number of passengers, providing adequate life-boats and life-preservers, prescribing the inspection of boilers, requiring the employment of competent pilots and captains, and providing other means of insuring safety. In certain grave emergencies, which fortunately seldom arise, provision is made under State laws for the inspection and quarantining of boats traversing our waterways. The sanitary equipment and management, though quite as important in their ultimate results, are, however, left to the direction and control of the companies. Official supervision by the sanitary authorities is the rare exception. The result is that those things most essential for the protection of health are liable to be slighted or entirely overlooked. The companies are not entirely responsible for these deficiencies. They are the purveyors to the people and aim to supply the demands of their patrons. These demands are the outgrowth of a pampered desire for elegant apartments, attractive surroundings, convenience and comfort, rather than the expression of the sanitary needs of the travelling public. When the public are instructed and know what to demand, corporations will not be slow to supply the deficiencies. What, however, may be accomplished indirectly and slowly by fostered public sentiment, can be promptly and satisfactorily brought about by authorized sanitary inspection.

Sanitary supervision of passenger traffic on rivers and lakes should be conducted under State or general Government laws according to jurisdiction, by State boards of health, or the central health authority. By concert of action of the authorities a standard code of regulations could be agreed upon, and its observance secured by means of periodic inspection. These regulations should embody the prime requirements of hygiene, and have particular reference to cleanliness, the water-supply, closets, berthing, ventilation, heating, lighting, and exceptionally the provisional care and disposal of the sick with contagious or infectious diseases, isolation, and disinfection.

More than the ordinary forms of cleanliness are required where the public assemble at will, and where discrimination in regard to them is not permissible and is not even possible. This requirement applies, of course, to the cabins, state-rooms, closets, and other enclosed spaces. Besides the ordinary forms of uncleanliness, there are the insidious and more potent forms to guard against which are derived from diseased persons. Persons from the sick-chamber carrying with them the fomites of dangerous diseases, and even the unsuspected sick themselves, may convey infection to public apartments, state-rooms, to the drapery, beds, bedding, and like absorbent materials. Tuberculosis, the more dangerous because its subjects constantly mingle with the pub-

lic, is liable to be spread by means of the disease-bearing sputum.

For the protection of the public, cleanliness should conform to a high standard. Not the glossing over of the surface, nor the perfunctory performance of a conventional practice, but a thorough, radical cleansing, or house-cleaning, the cleaning of paint, the scrubbing of woodwork and floors, the beating and steaming of carpets, drapery, and coverings, should be done at stated intervals as supplemental to the daily cleansings.

It is no unreasonable exaction to demand that beds and bedding continually in use in confined apartments, by all sorts of persons of unknown antecedents, should be frequently aired and sunned, and occasionally radically purified by exposure in a steam chamber to a disease-germ-destroying temperature. This cannot be deemed an unnecessary refinement, when its object is to promote the public comfort and the public health.

Every vessel carrying passengers should, for convenience and economy, be fitted up with a chamber for disinfecting by dry and moist heat, so that the necessary treatment of articles can be regularly and systematically conducted.

The advantages for maintaining cleanliness upon river craft are exceptionally great. With perfect drainage, cleanly environment, facilities for ventilation, free use of hot water and steam, and motive power at hand for appliances, there can be no valid reason why ideal cleanliness should not be maintained on all passenger transports on rivers and lakes.

The provision and storage of the water-supply should be so supervised as to guard against impurity. The cisterns should be properly made and placed and protected, so as to guard against the sources of accidental contamination. They should be regularly cleaned to prevent any possible contamination from deposits which form in stored water. It would be much safer, particularly during the presence of an epidemic, to depend entirely on sterilized water for drinking purposes. Apparatus can be obtained for automatically sterilizing water in steam-tight chambers at a given temperature, and delivering it to air-tight receivers of any capacity. Thence it may be conducted to taps, passing on the way through coils surrounded by ice or cold water for reducing it to an agreeable temperature. If desired, the water may be filtered before being sterilized. The adoption of such a plan guards against the danger from impurities in water and ice, and settles satisfactorily a question which oftentimes causes much anxiety, by guaranteeing a certainty and reliability of result which often fails under ordinary management.

Under ordinary circumstances the closets may discharge through tubes directly into the river. But where passenger boats ply upon rivers the water of which is utilized for drinking purposes, the closets should be provided with movable water-tight receptacles or with latrines, the contents of which should be discharged only after thorough disinfection has taken place. The closets should be scrubbed with soap and water and occasionally disinfected before cleansing. The tubes will require swabbing out with disinfecting solution at regular intervals. Milk of lime is useful for this purpose. During the prevalence of cholera the strictest regulations for disinfecting should be enforced.

The cleanliness of state-rooms and berths should conform to a high standard. Clean linen and a tidy appearance are not the only essentials from a hygienic standpoint. Danger lurks in the beds and bedding used for long periods without an attempt at purification or even airing, although liable to be occupied by persons infected with dangerous communicable diseases and by those suffering from tuberculosis, without suspicion being excited. So long as ignorance and unconcern as to the true condition exist, cleanliness will be restricted to the ordinary usages. It remains for the sanitary inspector to point out the fault and insist upon its correction. Public sentiment, when once established, will demand this needed innovation.

Pillows, beds, and bedding are, in fact, only superficially cleaned, except in special cases, for the reason that they cannot be washed without injury. But this is not an insuperable difficulty, as these articles can be purified by a convenient, safe, and effective method through the use of heat in closed chambers. A disinfecting chamber is an essential part of the outfit of every passenger transport, and should constantly be brought into use, as a most indispensable adjunct to the conventional methods of cleansing.

There need be no difficulty in meeting every sanitary requirement as to ventilation, heating, and lighting, as the conditions are favorable to the execution of satisfactory plans. By means of funnels, shafts, and steam-driven fans, fresh air can be introduced in the cabins and apartments below deck in ample volume to maintain the standard of purity, and by means of steam coils or radiators the air can be maintained at a healthful temperature. By combining the system of ventilation by propulsion with that by extraction, the best results can be obtained. The motive power can also be utilized in generating electricity for supplying incandescent electric lights, which neither deprive the air of its oxygen nor impart to it impurities.

Arrangements should be matured for the provisional care of persons sick with contagious or infectious disease. Whenever such cases are detected, they should be promptly separated from the rest of the passengers and confined in an apartment specially set apart for the purpose, until the proper authorities at the place of landing are notified. After removal of the sick everything liable to contamination should be subjected to thorough disinfection in the manner already indicated.

During an epidemic of contagious or infectious disease the strictest vigilance will be required to protect the travelling public from the danger of contact with the sick. Hence it is especially necessary at such times to place passenger boats under strict sanitary supervision. It may even be necessary, under special circumstances, to require sanitary inspections to be made at the points of departure and destination. When cholera or small-pox is prevalent the lines of communication from the infected district may spread disease broadcast through passengers or fomites, and therefore, as a precautionary measure, close inspection should be practised. The sick, suspicious cases, and suspicious baggage should not be received on board. Should sickness occur on board, arrangements for taking care of and disposing of the sick, for disinfection, for protecting the well, similar to those advised in the case of railroad trains under like circumstances, should be carried into execution.

As the object of inspection is to detect sickness or whatever may harbor disease, to insure the necessary provision for any emergency that may arise, and to see that every sanitary requirement is carried out, this service is the main dependence in protecting health and in preventing the spread of diseases through the avenues of travel, and should therefore be made as efficient as possible. The captains of steamboats should be held to a strict accountability for the observance of all needful sanitary regulations. Inspection is the means of determining whether this obligation is faithfully performed.

William H. Ford.

SAN REMO. Brief mention of this Mediterranean resort has already been made under the article "Riviera" in Vol. VIII. of the HANDBOOK. But the universally acknowledged importance of the place, and its recent growth and development as an international winter sanitarium, justify a somewhat fuller account of its peculiarities than has been given in the article referred to.

The writer, having recently spent several weeks at San Remo, was able to report, in the main, favorably on its claims to be considered as a first-class winter health-resort. (*The Medical Record*, August 13 and 20, 1892.)

In his report, the writer has stated that San Remo is the largest, the best, and in all respects the most important, winter station on the Italian Riviera. Its natural advantages, *i.e.*, situation, protection from winds, etc., give it a winter climate fully as mild and equable as that of Mentone. In addition thereto this little Italian town has

been fairly well piloted of late years as regards the introduction of a number of substantial improvements. Thus, since the new aqueduct has been completed, no better drinking water is found in all Italy than at San Remo. New streets have been constructed, old ones have been repaved, cosey villas have been erected, and well-equipped modern stores have sprung up. Cafés, restaurants, a theatre, spacious hotels with attractive gardens, all point to the flourishing condition of this city. Then, again, it speaks well for the common sense of the community that no attempt has been made to create a sudden boom, but that the people have been content to promote the healthy, steady growth of their town, which is so largely dependent on the continued good will of the foreign element.

At present, under the powerful impulse of a new municipal administration, at the head of which stands the energetic Syndic (mayor) Signor Alessandro Escoffier, serious attention is being given to the introduction of a system of needful sanitary reforms, which, if intelligently carried out, will make San Remo one of the healthiest, as it is now one of the most popular, winter resorts on the north shore of the Mediterranean.

Like so many Riviera towns, San Remo is picturesquely situated on several slopes running down to a beautiful bay. The bay forms an inlet of the Gulf of Genoa, and where the new town stands it is shaped somewhat like an elongated S. The new mole which protects the shallow little harbor projects like a hook into the sea. The larger bay, extending beyond the city limits, stretches out for over four miles, with four minor indentations, in the shape of a graceful crescent. The eastern boundary is formed by a bold headland called Capo Verdo (350 feet high), while the western extremity is marked by the still higher headland of Capo Nero (800 feet high). Hills and mountains rise from these promontories, protecting the town almost as effectually as Ospedaletti is sheltered. Monte Bignone towers up back of the city to the height of four thousand two hundred and seventy feet. The hills are green with olive-trees, firs, pines, and large chestnut-trees, so that the peculiar splendor imparted by a barren background of bare rock, as at Monte Carlo and Mentone, is not here seen, where a softer character is found in all the lovely landscape.

San Remo faces southwest. It lies about thirty-one miles in an easterly direction from Nice, sixteen miles from Mentone, and eighty-five miles west of Genoa.

The biting north winds and the dreaded mistral are, therefore, never *severely* felt at San Remo. But to say that they are quite unknown there is a wilful misrepresentation. During the writer's stay at San Remo he was treated to dusty and violent east winds, which were almost as disagreeable as the true mistral at Hyères and Cannes. Nevertheless the general mildness of the winter climate at this place is amply shown by the luxuriant semi-tropical character of its vegetation. There is no doubt that the triple rampart of its encircling mountains gives it very substantial protection, more particularly because the hills are not here cleft by deep gorges and wide open valleys, as is the case at most of the resorts on the Riviera.

Fig. 549.—View of San Remo from the Mediterranean Sea.

In addition to its climatic advantages, it is gratifying to know that San Remo is a healthy town. It has an average death-rate of less than twenty per thousand of the native population. Mention may here be made of the fact that the authorities were erecting a public disinfectory at the time of the writer's visit. It is intended that in all cases of contagious maladies, whether occurring in hotels, lodging-houses, or villas, the entire clothing outfit, linen, bedding, etc., are to be sent to the disinfectory, where they will be subjected to the action of superheated steam, applied in the efficient manner devised by modern science. This certainly shows that the interests of visitors are to be cared for by those aware of the value of sanitation, which is more than can be truthfully said of certain other alleged health-resorts on the Riviera.

It must not be concluded from these remarks, however, that an altogether ideal sanitary state was found by the writer in San Remo. Hygienic improvements are called for in the direction of better drainage and sewerage, improved methods of drinking-water distribution, etc. But the fact remains that San Remo is salubrious, and that

the foreign colony has nothing to fear from local fevers or other endemic maladies.

Through the kindness of Dr. Hassall the writer is able to present to the reader the following reliable meteorological data, based on eleven years' consecutive observation by that careful observer:

TABLE SHOWING THE WINTER SEASON CLIMATE AT SAN REMO.

	SEASON.[1]											
TEMPERATURE.	1879-80.	1880-81.	1881-82.	1882-83.	1883-84.	1884-85.	1885-86.	1886-87.	1887-88.	1888-89.	1889-90.	*Mean of* 11 *years.*
Mean shade	52.00	54.30	54.40	52.58	53.98	52.72	52.82	52.30	49.61	52.02	52.23	52.63 Fahrenheit.
Mean maximum shade	57.69	59.70	58.60	56.93	57.99	56.62	56.86	56.10	54.87	56.28	57.05	57.15 Fahrenheit.
Mean minimum shade	45.76	48.60	48.17	46.76	48.07	46.08	46.32	45.14	45.28	45.83	45.80	46.53 Fahrenheit.

[1] The season lasts from November 1 to April 30. [2] In the first three years the mean sun-heat in air and in vacuo is based on the days on which the sun actually shone, but in the following years it is spread over all the days of the season, even those on which the sun did not shine; hence a lower mean is shown in the eight later years. [3] Every day on which as little as the $^1/_{100}$ of an inch of rain fell is counted as a rainy day.
[4] Based on three daily observations, at 9 A.M., 9 P.M., and 3 P.M.

In the way of amusements San Remo does not come up to Nice, but perhaps this is an advantage to real invalids in quest of health.

The walks in and about the town offer sufficient attractions to make them enjoyable, although there is not the great extent and variety found at Nice and Cannes. Mountain climbing and donkey rides may be profitably indulged in by the more robust. It is quite unfortunate that the railroad has been allowed to run close to the shore, as the town has thus been robbed of a sea promenade that might have rivalled the famous Promenade des Anglais at Nice. Excursions in carriages are less popular here than at other Riviera places, for the roads are dusty and offer few compensatory inducements in the way of beautiful views.

There is a singular unanimity of opinion among medical and other competent writers relative to the advantages of San Remo as a winter health-resort. Dr. Hassall[1] has given the following fair *résumé* of the characteristics of the climate: "It is moderately warm during the winter, even in the shade, the temperature being fairly equable. It is very sunny; there are but few days on which the sun does not shine, and the duration of the sunshine is very considerable. In consequence of the power of the sun and the duration of the sunshine the air is for the most part clear, the sky bright, and there is abundance of light. There are but few days on which rain falls, and the air is moderately dry. Owing mainly to the sea and land breezes, the air is kept in movement day and night, and is consequently refreshing and exhilarating. The combined effect of these several characteristics is that the climate of San Remo is, during the winter season, moderately stimulant and decidedly tonic. A climate possessing the qualities above mentioned cannot fail to exert a very powerful influence on the functions of the body, for good or evil, in a great variety of diseases. Owing to the mildness of the climate there is less wear and tear and less strain. The several functions are performed in a more moderate and uniform manner. There being less expenditure of power and less waste, a smaller quantity of food is required, and the stomach has less work to do. The circulation, in particular the heart and its vessels, is exempt from the severe strains entailed by extremes of cold and heat, and which in themselves are often injurious, and not unattended with danger. The action of the sun on the human body is very complex; the effects are not confined to the warmth derived from its calorific rays; the luminous and chemical rays all exert powerful effects. The sun acts as a stimulant to most of the bodily functions: to elimination, secretion, and absorption; it determines many chemical changes, and promotes sanguification and the coloration or bronzing of the skin."

San Remo has many excellent hotels, like the West End and the Hôtel des Anglais, where prices are rather high. For slender purses, less pretentious establishments exist in plenty. The expense of living well is as high as elsewhere on the Riviera, although Italy is, in general, a rather cheaper country than France. Foreigners are always expected to pay more than natives, but actual extortion is not a common practice at San Remo.

Respecting the class of invalids likely to derive more or less benefit from a winter's residence at San Remo, it is not necessary to repeat the indications previously formulated with regard to Riviera resorts generally. Physicians who intend to send patients to San Remo, will do well to bear in mind, however, that this Italian station is at present very largely patronized by Germans, and that English-speaking invalids do not predominate as at Hyères, Cannes, and Nice. An excellent account of San Remo has been quite recently published by Dr. Rieth.[2]

SANTONIN-OXIM.—A derivative of santonin, obtained by the action of hydrochlorate of hydroxylamine, in alcoholic solution, upon santonin. Its chemical formula is $C_{15}H_{18}O_2NOH$, that of santonine being $C_{15}H_{18}O_3$. It is a white crystalline substance, having a melting point

of 323° F. It is scarcely soluble in water, but soluble in alcohol and ether, and in weak alkaline or weak acid solutions.

Santonin-oxim is recommended as a substitute for santonin, as it is said to be free from any toxic properties, its anthelmintic action being effected without any influence on the general system. The dose for children of two or three years is one grain; from four to six, one and one-half grain; six to nine, two grains; and for adults, five grains. This quantity is to be given in two portions, an hour intervening between them. The dose should be repeated for two or three days, and followed by a purgative. *Beaumont Small.*

SARCOMA AND CARCINOMA, CURATIVE TREATMENT OF, BY ERYSIPELAS.—There is perhaps no subject in the whole field of medical science that has received a larger share of thought and careful investigation than cancer; yet when we sum up the results of all this, so far as their actual practical value is concerned, we cannot but be struck with their insignificance.

It is true that we know more about the pathology of cancer and its various anatomical forms than ever before; we even realize the importance of early diagnosis and operation better than our predecessors. Yet when this has been said, in seventy-five per cent. of all cases of cancer that have commanded the best surgical and medical skill, the tumor recurs, becomes inoperable, and the patient is left to a fate the more horrible as it is slow and sure.

It has been with a view of benefiting such hopeless cases as these that erysipelas inoculations have been tried. No extravagant and ill-founded claims that erysipelas can cure all cases of malignant disease are made. Yet at the present moment sufficient clinical and experimental data exist to establish beyond question that erysipelas possesses an active principle that in some way is *antagonistic* to *sarcoma* and to a less degree to *carcinoma*; and in a certain, and by no means insignificant, proportion is *curative* of the same.

In addition to the personal experiments carried on in a large series of cases during the past two years, I have collected as far as possible all the evidence from other sources, and my results have very recently been published in the *American Journal of the Medical Sciences* (May, 1893), where the details of the cases may be found.

In a paper published in the *Annals of Surgery*, September, 1891, entitled "A Contribution to the Knowledge of Sarcoma," I referred at some length to the curative effect of erysipelas upon sarcoma, and reported the results of three original cases treated by inoculation. In all of those cases I failed to produce a true erysipelas, but the frequently repeated injections of pure liquid cultures had the effect of temporarily checking the growth.

Since that time I have continued my investigations in fifteen additional cases, including the cases treated by the toxic products of erysipelas. In the spring of 1890, while making a collection of all the cases of sarcoma operated upon at the New York Hospital during fifteen years, I found a case that convinced me that erysipelas possessed a powerful principle antagonistic to sarcoma.

Whether or not this principle could be isolated or utilized in the practical treatment of sarcoma, was quite another question, yet one of sufficient interest and importance to lead me at once into making a thorough study of the subject.

The case referred to was very briefly as follows: A round-celled sarcoma of the neck occurring in a German aged thirty-one. Five operations had been performed by Dr. William T. Bull within a space of three years.

At the last operation, a very extensive one, it was found impossible to remove all of the tumor, and a portion was left attached to the carotid artery. The case was regarded as hopeless.

The tumor had already begun to grow when a well-marked attack of erysipelas accidentally occurred, followed shortly after by a second attack. During the course of the erysipelas the remains of the sarcoma disappeared; the wound, originally, five inches by four, and left open, healed rapidly, and the patient was seen both by Dr. Bull and myself alive and well *seven years* afterward; at which time a photograph, of which the accompanying cut is a faithful copy, was taken.

FIG. 550.

The diagnosis in this case had been repeatedly confirmed by well-known pathologists, and there was no possibility of attributing the cure to any other cause than erysipelas.

If erysipelas, a disease supposed to be produced by a specific organism, could, when occurring accidentally, cure a case of undoubted sarcoma, it seemed fair to presume that the same benign action would be excited in a similar case if erysipelas could be artificially produced.

Having satisfied myself that the mortality of erysipelas uncomplicated was very slight, I determined to inoculate the first case of inoperable sarcoma that should present itself.

On May 1, 1891, I inoculated a case of recurrent sarcoma of the neck and tonsil, kindly referred to me by Dr. William T. Bull. The subsequent history of the case is briefly as follows:

The patient was an Italian, thirty-five years of age, operated upon previously in Rome by Professor Durante, and in April, 1891, by Dr. Bull, at the New York Hospital. At the latter operation the growth was found too extensive to remove. At the time of my first inoculation the tumor of the neck was growing, and the right tonsil was the seat of a tumor the size of a hen's egg and almost completely blocking up the pharynx. Solid food could not be taken, and liquids frequently regurgitated through the nose. The patient's condition was very bad. He was emaciated and cachectic. The dangers attendant upon an attack of erysipelas were explained to him, and in view of the hopelessness of his condition and the impossibility of obtaining further surgical relief, he consented to erysipelas inoculation.

The details of the earlier treatment are given in a former paper,* and I will not repeat them here; suffice it to say that the inoculations were made by injecting small quantities of bouillon cultures (½ to 2 c.c.) into the tumor itself, scarification (Fehleisen's method) having proved unsatisfactory. The inoculations were continued at short intervals during May and a part of June. Slight

* Annals of Surgery, September, 1891.

local and constitutional reaction followed the inoculations, the tumor of the neck diminished in size, and the general condition improved. The tonsil tumor was also smaller and the voice much better.

During August and September the treatment was discontinued, and the tumors at once began to increase in size and the general coudition to deteriorate.

October 1st, they had reached their former size, and the patient's condition was little different from that at the time the inoculations were begun. At this time I succeeded in getting a culture of streptococcus erysipelatis kindly brought me by Dr. Farquhar Ferguson direct from Koch's laboratory, and I decided to make a further trial. One-half a cubic centimetre of a fresh culture was injected into the tumor substance. Up to this time he had had no attack of true erysipelas, the slight local reaction passing away in from twenty-four to forty-eight hours, and the temperature thereupon becoming normal. Within an hour he had severe pain, nausea, vomiting, and a chill lasting forty minutes. His temperature rose to 105° F., and within twelve hours a patch of perfectly typical erysipelas, the size of the palm of the hand, appeared upon the neck. This gradually extended over the face and head, and met upon the opposite side.

The disease ran the usual course, and I made little effort to check it, save to apply some ichthyol upon the forehead to prevent its extending to the scalp (which, I may add, it failed to do). At the end of ten days the pulse and temperature had become normal. The tumor of the neck began to break down on the second day, and discharged until the end of the attack. The discharge was not pus, but resembled the caseous material of a tubercular gland. The outlying nodules disappeared by absorption without breaking down. The tonsil tumor was smaller, but the diminution in size was not great. At the end of two weeks the tumor of the neck had disappeared, and there remained only the induration from the previous operation. The appetite began soon to improve and he gained rapidly in flesh and strength. There has been up to the present time (July, 1893) no return of the tumor in the neck, and although the tonsil tumor has remained about the same in size, its malignant character must have been destroyed, as sarcoma of the tousil is known to be rapidly fatal.

The patient's general condition at present (more than two years) is excellent, although he is suffering from a confirmed morphine habit which he had contracted previous to the inoculations.

Case II. *Periosteal Sarcoma of the Lower End of the Femur.*—The patient, aged sixteen, had been treated at several hospitals for supposed tubercular disease of the knee. An exploratory operation by Dr. R. F. Weir and microscopical examination proved the trouble to be sarcoma. Amputation was advised, but absolutely refused by both parents and patient. Erysipelas inoculations were tried and repeated at short intervals during four weeks. Injections of pure bouillon cultures, 1 to 2 c.c., were made directly into the tumor. Well-marked reactions followed within one-half to two hours after the injections, the temperature frequently rising as high as 104° or 104½° F. The general symptoms corresponded to those seen at the beginning of an attack of erysipelas, yet no visible erysipelas was produced, and the reactiou usually subsided in twenty-four to forty-eight hours. The tumor, which was very large (size of man's head) and ulcerated in part, showed temporary improvement, but owing to the size of the tumor and the poor condition of the patient, as well as to the failure to produce a true erysipelas, the injections were discontinued. Death occurred from exhaustion four months later.

Case III. *Periosteal Sarcoma of Spine (Upper Dorsal).*—The patient, a woman aged twenty-six, had injured her back by a fall about two years previously, and two operations had been performed and were followed by rapid recurrence, before the erysipelas was tried. Cultures from three different sources were tried, yet I was unable to produce erysipelas. The tumor became much softer and more movable, and slightly smaller. Only five injections were made; they were then discontinued on account of the failure to produce erysipelas, and a third operation was performed (August, 1891). The disease recurred quickly and developed with great rapidity. Paralysis of the lower extremities soon followed, and death occurred six months after the last operation.

These two cases are, so far as I have been able to ascertain, the only cases of bone tumors where inoculation has been tried; although Dr. Gerster reported at the Surgical Society, a year ago, a most remarkable case of sarcoma of the lower end of the femur, with amputation at the trochanter minor, followed by rapid recurrence in the stump. An attack of *accidental erysipelas* ensued a few weeks later, whereupon the tumor entirely disappeared, and the patient has been seen by Dr. Gerster five years afterward, free from recurrence.

This case of Dr. Gerster's is alone sufficient to demonstrate that the curative effect of erysipelas may be exerted upon sarcoma of the bone as well as upon sarcoma of the soft parts.

Cases IV. and V., the one a very extensive carcinoma of the face, and the other a very large sarcoma of the back (17½ × 18½ inches) deserve but brief mention, for the reason that the cultures were much attenuated, and not only was no erysipelas produced, but the reaction was so very slight that the injections were soon discontinued.

Case VI. *Large Sarcoma of Back and Groin—Operation (Groin Tumor)—January*, 1892— *Recurrence in One Month—Successful Erysipelas Inoculation—Entire Disappearance of Both Tumors in Two Weeks—Recurrence Three Months later—Second Inoculation—Second Disappearance—Recurrence—Final Disappearance under Injections of Toxic Products of Erysipelas—Patient well and free from Recurrence July* 14, 1893.*—The patient, a German, forty-six years of age, cigar-maker, with a good family and personal history, applied at the Hospital for Ruptured and Crippled early in January, 1891, for treatment for a swelling in the right groin.

At that time there was a tumor the size of a goose-egg —hard, slightly nodular, deeply seated in the region of the inguinal glands, without any signs of an inflammatory nature. Hernia could easily be excluded, and the usual causes of an adenitis were absent. The patient had first noticed the tumor five months before; it had slowly but steadily increased in size, and was slightly painful. I made the diagnosis of malignant disease, in spite of the fact that careful questioning failed to elicit any history of a primary tumor elsewhere. A few days later I operated upon the tumor of the groin, at the Post-Graduate Hospital. The tumor was found to consist principally of degenerated glandular tissue, but no pus was present. The microscopical examination was unsatisfactory. While putting on a spica bandage I discovered a large flat tumor in the lumbar region of the back, measuring six inches by four, elliptical in shape, and projecting from the normal surface about one-half to one inch. It was very hard and nodular, presenting numerous tuberosities. Its color varied from a bright red to a plum color. It was freely movable, and was evidently situated entirely in the skin and subcutaneous tissue. The patient stated that it had been there five years, but having caused him little inconvenience, he had paid slight attention to it.

Aside from an indefinite history of injury in the army in 1870, no cause could be found for the tumor.

Soon after leaving the hospital Dr. George H. Fox kindly saw the case with me, and his diagnosis was sarcoma of the skin. A photograph was taken at the time, February, 1891, and a copy of it is shown in Fig. 551.

Shortly afterward I removed two sections of the tumor under cocaine, for microscopical examination, and the diagnosis of sarcoma was confirmed by the careful examination of Dr. Farquhar Ferguson, the pathologist of the New York Hospital. At this date, February 22, 1892, the tumor of the groin had already recurred and was growing rapidly. The tumor of the back was also increasing in size. In view of the rapid recurrence in the

* As this is, perhaps, the most interesting and suggestive of my cases, it is given somewhat in detail.

groin and the large size of the tumor of the back, the patient was advised, both by Dr. Bull and myself, to have erysipelas tried. After some deliberation he consented, and on April 12, 1892, I began inoculations.

During the first three weeks of treatment the inoculations were made at intervals of two or three days. Well-marked constitutional reaction followed, accompanied by slight local redness at site of puncture; the condition returning to normal at the end of twenty-four to forty-eight hours. The effect on the tumor was a perceptible decrease in size; there was no formation of pus, nor was there any breaking down of the tumor tissue. At the beginning of the fourth week I used a new and stronger culture. The first injection of 0.7 c.c. produced a reaction quite similar to that obtained from the other culture. The second, of 1½ c.c., two days later, produced a perfectly typical attack of erysipelas, both in the back and groin (injections having been made in both places).

Four hours after inoculation the patient had a very severe chill, with nausea and vomiting and marked prostration. The temperature rose to 105½° F. and the pulse to 130. The subsequent history was that of a typical but severe attack of erysipelas. The disease did not extend over a very large area, although no measures were taken to check it.

Fig. 551.—Sarcoma of Back and Groin. Entire disappearance after erysipelas inoculation. (Coley.)

From the beginning of the attack the change that took place in the tumor was nothing short of marvellous. It lost its lustre and color, and had shrunk visibly in size within twenty-four hours. Several sinuses formed on the second day and discharged necrosed tumor tissue. A few days later the tumor of the groin, which was about the size of a goose-egg, and very hard when the inoculations were begun, broke down and discharged a large amount of similar material. This continued for two weeks, after which time the sinuses gradually closed. The most projecting portion of the tumor of the back ulcerated over an area one and a half inch in diameter, but this rapidly healed.

Three weeks from the date of the attack both tumors had *entirely disappeared*, and there was scarcely any induration remaining. The patient's general condition improved rapidly. He gained seven pounds in twelve days. There was no recurrence of the tumors until July 1st, when a small nodule, the size of a pea, appeared at the site of the former tumor of the back.

July 18th, there were six small nodules within an area of from two to four inches, the largest of which was seven-eighths of an inch in diameter.

On July 3d, injections of the fluid culture were begun and continued at intervals of two or three days for several weeks. Some of the nodules disappeared entirely, and the tumor, as a whole, was held in check, but as soon as the injections ceased the growth was very rapid. A second attack of erysipelas was not produced until November 14th.

At this time the tumor in the back had nearly reached its original size, having increased to 5 × 3½ inches, with a projection of ½ to ¾ inch. The tumor in the groin was the size of an English walnut.

On November 14th, 1.5 c.c. of a culture two weeks old (obtained early in October from a very virulent case of erysipelas) having been previously tested upon rabbits, was injected into the tumor in the back. (Injections of this same stock, except that the cultures were younger, had been used for three weeks without producing erysipelas.)

Fourteen hours after the injection a severe chill occurred, and a few hours later an area of well-marked erysipelas appeared. Several inches from the point of inoculation the disease ran a typical course, subsiding at the end of a week.

The area of erysipelas never exceeded eighteen inches in diameter, although no attempt was made to limit it, and the condition was at no time serious.

The changes produced upon the tumors by this second attack were no less remarkable than those observed in the first attack. Within twelve hours of the onset the tumor became dull and lustreless, and began to break down. Four or five sinuses formed from which degenerated tissue escaped during and after the attack of erysipelas.

At the end of thirty-six hours the tumor had diminished one-half, and at the end of a week there was nothing left save a slight induration at the site of the tumor in the groin: it had entirely disappeared by absorption *without* breaking down.

It is worthy of careful note that in this case the erysipelas was chiefly confined to the right buttock and at no time extended within several inches of the sarcoma either in the back or groin, yet the effect was quite as marked. Two weeks later a recurrence appeared in the back, and grew rapidly.

The latter part of December the patient had a third, but much less severe, attack of erysipelas, in this case spontaneous, probably from the streptococci remaining in the skin, at the site of the previous attack. During the next three weeks two similar attacks occurred in the same locality.

The effects of the last attacks upon the tumor were less marked and more temporary. In January, 1893, I removed the focus of disease in the back. The wound was left open and partially covered with Thiersch's skin grafts. Most of the grafts failed to take, and the wound healed badly. Sarcomatous granulations appeared three weeks after the operation and the tumor in the groin recurred. Injections of *filtered cultures* of erysipelas were then begun. The injections were made into the

groin tumor only, and were repeated every forty-eight hours.

Slight local and considerable constitutional reaction followed, but the condition usually became normal within two days. The flabby sarcomatous granulations in the back at once began to disappear and the wound rapidly healed. The tumor in the groin, which had reached the size of an English walnut, also gradually decreased in size, and at the end of four weeks had entirely disappeared. The patient has regained his normal weight, one hundred and sixty-five pounds, and has resumed his work. No return of the disease, July 14, 1893.

Whether or not the tumor will recur, it is as yet impossible to say, but the case is by far the most important of all, as it illustrates not only the effect of true erysipelas upon a case of sarcoma, but also proves that *one* successful inoculation does not render the patient immune to subsequent inoculations, and furthermore, that the toxic principles of erysipelas contained in the filtered cultures may still exert a curative effect after several previous attacks of true erysipelas.

Case VII. *Sarcoma of Breast—Inoculation of Erysipelas after Seven Recurrences—Partial Disappearance of the Tumor—Second Successful Inoculation Four Weeks after First—Effect upon Tumors Temporary.*—The history of the case is given in detail in the paper already referred to.

The patient was a female aged thirty-eight years, single and without any family history of cancer. The tumor had first appeared five years before, and was operated upon for the first time in 1889. It recurred promptly, and the subsequent history up to June, 1892, when inoculations were begun, was simply a repetition of operation and recurrence. The last operation was performed by Dr. W. T. Bull, in April, 1892. On June 1st, three separate tumors had appeared at site of cicatrix, and in view of the hopelessness of benefit from further operation, inoculation was suggested by Dr. Bull. The first inoculation was made June 2d, 1.5 c.c. of a culture five weeks old was used; two hours later a severe chill occurred, and six hours from the time of inoculation the temperature had risen to 104.2° F. Twelve hours after inoculation an erysipelatous blush extended a distance of seven inches from the point of inoculation. The disease ran a typical course of a week's duration.

The tumors broke down on the second day and discharged degenerated tissue, as in the preceding cases. The tumors decreased very much in size, one of them almost disappearing. They soon began to grow again, and others appeared in neighboring parts. The inoculations were repeated, but a second attack of erysipelas was not produced until July 2d.

June 30th. At this time the lower tumor was scraped out with a sharp spoon under cocaine, and ten minims of culture, two weeks old, put into the wound. Twenty-six hours later she vomited and had chilly sensations, but no distinct chill. The temperature was 99.4°, and steadily rose until 12 M., July 4th, when it had reached 104°. It remained high for several days, reaching 105° on two days.

The erysipelas spread over a considerable portion of the back and down the left arm to the hand. The temperature did not fall to normal until the eleventh day of the disease. Although all of the nodules were diminished in size and some even disappeared, the check proved but temporary, and they soon began to increase in size. Although the last attack of erysipelas was a severe one, the recovery was very rapid, and the general condition was soon as good, if not better, than before the attack. The tumors grew very rapidly and were exceedingly painful. In October there were three distinct tumors, the largest of which was as large as a cocoanut, without ulceration, very soft, in consistence almost fluctuating. There was a second tumor, as large as a large orange; it had a fungoid appearance, with a small pedicle. These tumors were removed by operation the latter part of October. Recurrence quickly followed.

In February, 1893, she developed a spontaneous erysipelas at site of previous attack in the preceding July. The attack was as severe as the former ones and the effect upon the tumor was marked, yet the benefit proved temporary and the tumor grew as rapidly afterward. It is very large at present and the condition of the patient hopeless. The character of the sarcoma in this case was very different from the common forms. In consistence it was so soft that it furnished all the evidences of fluctuation. It was composed of mucoid gelatinous material, and vascularity was nearly absent.

This case, along with one of a similar type of sarcoma recently treated by the toxic products of erysipelas, would seem to show that this variety (myxo-sarcoma) is less affected by erysipelas than the more usual forms.

Case VIII. *Recurrent Carcinoma of the Breast—Repeated Inoculations of Erysipelas—Diminution in Size of Tumor—Improvement Temporary.*—The tumor occurred in a woman forty years of age, who was married and had had children. Predisposing causes were to be found in a family history of cancer, and also in a personal history of mastitis. The tumor was first noticed one and a half year before. Four operations had been performed within less than a year. The tumor at the time of inoculation was the size of a goose-egg, five by three inches, and occupied the upper part of the region of the left breast. The growth was markedly protuberant and ulcerated over an area the size of a silver half-dollar. A thin, serous discharge, very profuse, necessitated frequent dressings. There was also a hard tumor, the size of an egg, adherent to the skin on the right breast, which was unmistakably carcinoma.

Inoculations were begun August 1, 1892, and continued at short intervals for two months. Moderate constitutional reactions followed the injections, and there was partial degeneration of the tumor, and considerable diminution in its size. The general condition of the patient was perfect, and not perceptibly the worse for the treatment. The reaction usually passed away in twenty-four to forty-eight hours, and the patient was able to be up and out most of the time. I did not succeed in producing a true attack of erysipelas, although I used the same cultures as in the preceding case. The inoculations were discontinued in the early part of October, and the tumor began soon to increase in size.

Case IX. *Recurrent Carcinoma of the Cervical Glands—Repeated Inoculations—Partial Degeneration of Tumor.*—The patient was a man fifty-five years old, operated upon by Dr. Frank Hartley, for a large carcinoma of the neck, in July, 1892, with rapid recurrence following,

He was treated for three weeks in October, 1892, at the New York Cancer Hospital Cottage, with repeated inoculations of a pure culture of erysipelas. Marked reaction followed, but erysipelas was never produced. The larger tumor (small egg) broke down, and for several days there was considerable discharge of degenerated tissue, and the tumor decreased in size about one-third.

Case X. *Large Carcinoma of Inguinal Glands Following Amputation of Carcinomatous Penis one Year before—Repeated Inoculations—Temporary Improvement.*—The history of this case, as far as the erysipelas is concerned, is almost exactly parallel to the one just described. The tumor was the size of an orange, in the right inguinal region. The patient was seventy-five years of age, and very feeble, having chronic bronchitis and a weak heart. I did not succeed in giving him erysipelas, yet partial degeneration of the tumor followed the repeated injections of the streptococci.

Case XI. *Large Recurrent Sarcoma of the Neck—Erysipelas Inoculation—Death on Fifth Day.*—The patient was sixty-five years of age, and his general health had been much impaired both by the disease and by a very extensive and recent operation. After having failed to produce a reaction with injections of toxic products, as well as with cultures from same sources as previously used, I decided to inoculate with a new and virulent culture. A small amount, five grammes only, was used. A chill occurred six hours later, and the temperature rose to 102½° F. The condition was not serious until the third day, when he became rapidly worse, and died on the fifth day. The erysipelas had spread over neck and face.

The tumor had diminished very much in size without breaking down.

Case XII. *Sarcoma of the Foot and Thigh.*—M. G., aged thirty-two, female, single. Two years ago she noticed a small wart-like swelling on the inner side of the left instep. It ulcerated upon the surface and was twice removed or "tied off." It never reached a size larger than a cherry, and was not painful. In April, 1893, she came to the New York Cancer Hospital with a tumor in the left femoral region, the size of two fists and ulcerated in part. There was also a hard swelling, extending above Poupart's ligament to within two inches of the umbilicus, and from the median line to within two inches of anterior superior spine.

The tumor in the groin was removed in part by Dr. C. A. Powers, in April, 1893. One week after the operation I began injections of filtered cultures of erysipelas repeated every forty-eight hours. Good reaction followed a dose of two c.c. The effect upon the tumor (the one in groin had already recurred) had not become apparent when (two weeks after beginning of injection) the patient developed a spontaneous erysipelas in vicinity of the wound.*

The effect of the erysipelas upon the tumor was a temporary check to its growth, but as soon as the attack had subsided the tumor again began to grow rapidly. Two weeks later (at the date of writing) injections of the toxic product were again commenced, but with tumors so large and growing so rapidly, there is no expectation of permanent benefit.

In addition to these twelve cases, I have treated six others by the toxic products of erysipelas without attempting to produce erysipelas. These cases have not yet been published, as the experiments have, most of them, been recent and the cases are still under treatment. The results are already sufficiently important to deserve mention. For more than a year I have been trying to find some satisfactory way of isolating the active principles of erysipelas, in order to test their effect upon malignant tumors. If it could be proven that the same effect could be produced by these toxic principles as by the erysipelas itself, a very great step in advance would be made, since the danger element would be entirely eliminated and the necessity of isolating the patient would be avoided.

My first experiments were made with liquid cultures subjected to a temperature of 100° C. The reaction in these cases was very similar in character (although slightly less severe in degree) to that obtained by pure cultures containing the living streptococci. The effect upon the sarcomata was also similar, yet far less marked than in the cases where a true erysipelas occurred. It seemed probable that the action of heat might have changed the chemical relations of the products, and I determined to try cultures rendered sterile by *filtration* through porcelain without the use of heat. I was unable to obtain such a preparation for some time. In January, 1893, I began using filtered liquid cultures (without heat) prepared by Dr. Alexander Lambert, at the laboratory of the College of Physicians and Surgeons of New York. This preparation was made from cultures somewhat attenuated, and although a slight reaction was obtained, the effect upon the tumor was not apparent.

Early in February, 1893, Dr. Lambert made a new preparation in the same way from a fresh culture obtained from a fatal case of erysipelas, and I began at once using it in two cases of sarcoma.

Cases of Sarcoma Treated by Toxic Products of Erysipelas.—Case I.—Boy, sixteen years of age, German, with good family and personal history. He had a large inoperable sarcoma of the abdominal wall, strongly attached to the pelvis below and extending nearly as far as the umbilicus above. Its transverse diameter measured seven inches and its vertical five inches at the time I began the injection of the toxic principles of erysipelas (January 18, 1893). The tumor could be easily felt by the rectum, and was firmly attached to the pelvis. The general condition of the boy was bad, and marked irritation of the bladder was already present.

A section of the tumor was removed, and examination by the hospital pathologist showed it to be sarcoma. As the case was inoperable, it was kindly placed under my care by Dr. L. B. Bangs, with a view of producing artificial erysipelas. Before inoculating with erysipelas it was decided to try the effect of injections of filtered cultures, reserving inoculation until later, in case of the failure of the toxic principles. My first injection produced little reaction and no perceptible effect upon the tumor. Early in February I began using the stronger preparation referred to, and doses of 0.5 to 1 c.c. produced well-marked reaction, severe chill, and temperature rising to 103° and 104° F. The treatment was kept up until May 5, 1893, or a period of three months. The later injections were given at longer intervals than the earlier. The patient was confined to his bed but a few days of the entire time, and was about and out of doors most of the time. Careful measurements made from time to time showed the tumor to be steadily decreasing in size, and the general condition of the patient correspondingly improved.

June 1, 1893, the tumor has so far disappeared that it is no longer visible, and the patient states that it has entirely gone. Examination shows a small movable mass in the abdominal wall, at site of original tumor (just above pubes), measuring less than two inches in diameter. When the treatment was begun, February 1st, the measurements recorded were seven inches by five inches.

The boy has gained ten pounds during the last month, and all bladder irritation has disappeared. The later injections had to be increased somewhat in quantity, to produce the same reaction; but 1.5 c.c. was the largest dose given. Injection of 0.2 to 0.7 c.c. of toxic products of the bacillus prodigiosus were frequently given along with those of the erysipelas, and repeated trials showed that the reaction (and apparently the beneficial action upon the tumor) was greatly intensified by the combination. This mutual action of the germs themselves has been noted by Roger in experiments upon rabbits.

Whether the tumor will entirely disappear it is yet too early to state; yet there seems to be ground for hoping that the improvement will continue. The injections have all been made directly *into* the substance of the tumor, and there has not been the slightest softening or tendency to break down, as has frequently been the case where true erysipelas has occurred.

Case II. (Vide Case VI. above).—This case was the one already described. The toxic products were injected into the sarcomatous tumors which had recurred after they had twice disappeared through the action of erysipelas artificially produced. There was some reason for believing that their action would in this case be either *nil* or very feeble, but on the contrary the tumors disappeared, and at present, four months since the injections were discontinued, there has been *no recurrence.*

Case III. *Recurrent Sarcoma of Thigh.*—M. B——, aged fifty-five. In July, 1889, a small swelling was observed just above the patella on the left thigh. It was not painful, but grew slowly. In November, 1891, it was the size of an egg, and was removed by operation. Second operation done July, 1892; third, January, 1893.

Each recurrence was more rapid in spite of more extensive operations, and each tumor grew faster than the preceding. On March 12, 1893, examination showed a tumor two inches in diameter attached to skin, but movable upon deeper parts, situated just above outer condyle of left femur, in region of old cicatrix. Just above the patella there was an induration two inches in diameter; a little farther up there was a distinct separate nodule three-fourths of an inch in diameter.

The toxic products of erysipelas were begun March 12, 1893, and given in the same way as in the two preceding cases.

* The infection in this case undoubtedly came from a case that had been brought to the ward from the isolating cottage two months previously, before desquamation had ceased. In 1890, I made experiments with the scales following erysipelas, and streptococci were found alive two weeks after all symptoms and redness had subsided, showing that the usual time of isolation is insufficient.

Much larger doses were given, and even then no appreciable rise of temperature followed. The only reaction that followed was severe headache, general muscular pain, and weakness. Locally, the tumor became swollen soon after the injections, and later decreased in size.

While the *filtered cultures* (prepared without heat) were used, the tumors not only did not increase in size, but decreased considerably.

The smallest one could scarcely be detected after six weeks. At the end of eight weeks, having no more of the filtered culture on hand, cultures sterilized by heat were tried. A severer reaction, both general and local, followed. The temperature rose to 103.4° F., and the patient had a severe chill. The cultures were exactly the same as previously used, except in respect to the method of sterilizing—no heat having been used in the *filtered cultures*.

The injections were continued three weeks, but the tumor began to grow again, and on May 31st had attained the original size of March 12th. The tumors were then removed by the knife, with the view of removing the larger part of the disease, and in the hope of destroying the remainder with erysipelas. The tumors removed were of the soft myxomatous variety, similar to Case VIII., where erysipelas produced only temporary improvement; therefore the prognosis is not so favorable.

Case IV. *Recurrent Sarcoma of Hand* (Three Recurrences).—Female, aged twenty-two years. This case, a patient of Dr. Samuel Lloyd, was operated upon, the last time, in January, 1893. The disease very quickly recurred a few weeks after the operation, and grew rapidly.

Injections of toxic products of erysipelas (filtered cultures) were begun in March, 1893. The local reaction was well marked and the usual constitutional symptoms followed.

The reaction gradually became less severe and the toxic products of the bacillus prodigiosus were used, with the same effect as in Case I. The tumor has slowly but steadily diminished in size, and the case is still under treatment.

Case V. *Sarcoma of Back — Recurrence in Axilla.*—Treatment but recently begun.

Case VI. Vide Case XII. above.

The results from the use of the toxic principles of erysipelas in the limited number of cases described, are sufficiently encouraging to make further experiments very desirable. Similar experiments have been very recently carried on in Holland, by Dr. C. H. H. Spronck, Professor at the University of Utrecht, and published in the October, 1892, No. of the *Annales de l'Institut Pasteur*. Spronck and his co-workers treated twenty-six cases of malignant tumors with a preparation of the toxic products of erysipelas.

Although Lassar had previously tried, somewhat earlier, local interstitial injections of sterilized cultures of erysipelas in a case of lupus carcinoma (*Deut. med. Woch.*, 1891, No. 29), Spronck determined to push the same idea further.

While Lassar sought for *local* action, Spronck aimed to get the *systemic* action, and accordingly made his injections remote from the tumor, usually in the gluteal region or back.

He prepared his toxic products in the same way that Koch did tuberculin, heating liquid cultures to 100° C., after addition of five per cent. glycerine. The liquid was then evaporated to one-tenth its volume, cooled, and filtered through porcelain. This preparation was then tried upon animals. In certain doses, varying with the virulence of the cultures from which it was derived, when injected into the circulation of a rabbit it caused death in from twenty-four to forty-eight hours.

The more virulent the culture, the more rapid the death and the smaller the fatal dose. A dose of ten to fifteen cubic centimetres per kilogramme weight of animal, injected into the circulation, usually killed rabbits in from twenty-four to forty-eight hours.

The symptoms preceding death were elevation of temperature, loss of appetite, diarrhœa, albuminuria, and paresis of posterior extremities. No noteworthy changes were observed at autopsy.

Spronck then experimented upon tumors in dogs. Some of the tumors were benign, others malignant. Subcutaneous injections of the toxic products were made in two cases at a distance from the tumors. The doses were repeated several times and increased in quantity, yet no effect was observed upon the tumors. They were removed, and examination showed the one to be a lipoma and the other a carcinoma (of anus).

With five other dogs, however, there was a more or less marked effect upon the tumors. After several injections (remote from tumors) the color of the tumors became of a bluish-red and the tumors themselves were warmer and more sensitive to the touch. Subsequently there occurred a softening and necrosis of the neoplasms.

"In two cases these latter changes manifested themselves with astonishing rapidity." After the treatment had been continued a short time the remaining portions of the tumors were extirpated and examined. Two were found to be *sarcoma* and three *carcinoma*. In all there was found a condition of fatty degeneration and necrosis, with an infiltration of polynuclear leucocytes from the blood.

Spronck very properly admits that such changes frequently occur in malignant tumors; hence it would be difficult to prove the entire effect to be due to the injections; yet in view of the symptoms following the injection, and the change in the tumors dating from the beginning of such injections, a causative relation seems indisputable.

One of his experiments upon dogs is worthy of special note. A large dog, cachectic, had a *very hard* tumor the size of an infant's head, situated in the region of the right shoulder. It was a local recurrence from a small tumor which had been extirpated the previous year. On the fourth day of the treatment the tumor developed a slight swelling and at the same time it became a bluish-red color, warmer and more sensitive to touch. Shortly afterward the consistence of the tumor diminished, and on the eighth day fluctuation was present. Three days later the entire tumor was transformed into a soft fluctuating mass, covered only by the skin. Incision was followed by the escape of a voluminous sac filled with a puriform liquid in which were suspended necrosed fragments of tumor, which proved on microscopic examination to be composed of detritus of the tumor and a large number of leucocytes. Somewhat later the dog died.

The autopsy showed that of the entire tumor there remained only a small fragment the size of a pullet's egg, where the tumor had been adherent to the skin. Microscopical examination proved it to be *adeno-carcinoma*. There can be scarcely any doubt that these wonderful changes were produced by the toxic products of erysipelas, and when we reflect that the tumor was *carcinoma*, and not *sarcoma*, the significance is far greater.

With the co-operation of Meulen, Renssen, Salzer, and seven other physicians, Spronck extended his experiments to twenty-five inoperable malignant tumors in man—eight sarcoma and the remainder carcinoma.

The same preparation of toxic products already described was used, and the injections were made, without exception, at points *remote* from the tumor. The utmost care was used in these experiments, and the doses were very small. The effect upon the tumors was by no means constant. In a certain number there was no appreciable change; in a second class, they continued to increase in size, but the growth appeared retarded; in a third class, there was *complete arrest* of growth; and in a fourth *diminution* in size took place.

In the same patient with several tumors, the tumors did not diminish with equal rapidity; while some disappeared entirely, a total disappearance of all tumors present was not observed in a single case. In most of them the improvement was only temporary. The effect upon carcinoma was much less marked than upon sarcoma, still in one case (recurrent cancer of the breast) there was pro-

duced an almost complete absorption of the lymphatic enlargements, though they afterward returned.

The most favorable effect was observed in a case of inoperable *sarcoma* treated by Renssen. After several weeks' treatment the primary tumor, of very considerable size, *completely disappeared*, and the secondary tumors were much diminished in size.

They were no larger than a pea, with one exception, and that the size of a pigeon's egg. Failing to decrease further, they were extirpated. Sufficient time had not elapsed to determine whether or not a radical cure had been obtained.

The symptoms following the injections were very similar to those observed in my own cases, and already noted. Elevation of temperature varying with the doses used, and with different subjects, was the most constant symptom. In most cases the rise in temperature began four to five hours after the injections, never went beyond 103.1° F., and usually returned to normal at the end of twelve hours. In my cases, the temperature has a few times risen beyond 105° F., but usually it has ranged between 101° F. and 103.5° F.

I have frequently observed a much more rapid onset, a chill occurring within a quarter of an hour after the injection, quickly followed by a sharp rise of temperature. Nausea, vomiting, severe headache, general muscular pain, and malaise, were more or less constantly seen. Spronck found that the relative susceptibility of the different patients varied greatly, some being entirely refractory. I have noted the same thing in my cases, yet in one case that had failed to show any rise of temperature after frequent injections of my preparation of toxic products (sterilized without heat), showed a marked rise, 103.4° F., when cultures from the *same* source and of the same virulence, sterilized by heat, were used. The important difference, however, in the effect of the two preparations, was that the first, although producing less constitutional reaction than the heated cultures, caused a *diminution* in the size of the tumor (sarcoma), while the second failed to even check its growth. My experiments in this case, together with others carried on in 1892, with cultures sterilized by heat, have convinced me that a portion at least of the value of the toxic principles is destroyed by a temperature of 100° C.

Although I had practically arrived at this conclusion almost a year ago (before the publication of Spronck's cases), I was unable to obtain a good preparation of toxic products of erysipelas sterilized without heat, until February, 1893. My results, although they cover a smaller number of cases than Spronck's, are yet more remarkable. In one case the sarcomata have entirely disappeared under injections of toxic products, and the patient is still free from recurrence. In a second case, a very large inoperable sarcoma of the abdominal wall, the tumor has so far diminished in size that only a small nodule remains. In two others there was decrease in size, and they are still under treatment.

The remaining cases are too recent to more than mention. In one, however, the improvement has been very doubtful. The elaborate investigations of Roger with the toxic products of erysipelas, upon animals, recently published in the *Rev. de Méd.*, December, 1891, show that instead of a single toxic principle, the erysipelas germ grown in bouillon forms a considerable number of soluble products, some of which differ so widely from others that they are directly antagonistic. He further found that these toxic products were capable of killing animals in doses of 13 to 20 c.c. per kilogramme weight, and that they are precipitated by alcohol and destroyed by heat. He also found that *filtered* cultures *not heated*, in doses of 5 to 12 c.c. injected into the circulation of rabbits, exercised a predisposing action, making the animal more susceptible to inoculation. On the other hand, *heated* cultures (104–110° C.) rendered the animals immune. In extremely large doses these products produced a more or less chronic form of septicæmia, which caused death in periods varying from a few hours to several weeks. Space will not permit a more detailed account of these experiments. They are cited to prove that in the soluble products of erysipelas, we have a very powerful and complex combination of active principles; that some are directly antagonistic to others; and finally, that heat has a very decided effect upon them. Aside from the difference in the method of preparation of the soluble products of erysipelas, my experiments differ from Spronck's in the fact that he sought for a systemic action alone, whereas I have endeavored to obtain both systemic and local action by making the injections into the tumor, or its immediate vicinity, and I believe my results show this to be the better plan.

Spronck, in conclusion, says: "If in man, the results have been less satisfactory (than in dogs), one should not lose sight of the numerous difficulties that lie in the way of these first attempts toward a clinical application, or of the unfavorable conditions in which we have been placed, or finally, of the fact that in nearly all of the patients the tumors were in a very advanced stage." He further states: "I believe that I am authorized to conclude that the products of erysipelas, in certain cases at least, can act in a curative manner upon malignant tumors."

In addition to the 18 cases of my own, treated either by pure living cultures of erysipelas or by the soluble products, I have collected and tabulated all the reported cases of carcinoma and sarcoma in which erysipelas, either spontaneous or artificial, intervened. It is upon a careful study and analysis of these cases, as well as upon the more practical experience derived from my own cases, that my conclusions are based. Time will not permit me to go into these in detail, and I can do nothing more than give a brief summary of the results.

We find a total of 43 cases of malignant disease in which an erysipelas has occurred, either by accident or by intent. Of these 43 cases the erysipelas occurred accidentally in 26 cases, and was the result of inoculation in 17 cases (including my own); 20 cases were carcinoma, 19 cases were sarcoma, 4 either sarcoma or carcinoma. The immediate and final results were as follows:

Carcinoma.—Of the 20 cases, 3 were permanently cured. In addition, 1 case of probable carcinoma (Hutchinson's) was well five years after the attack of erysipelas. Of the remaining 16, 11 showed improvement which, although temporary, undoubtedly added to the life of the patient in most cases. One case (Janike's) died, as a result of the erysipelas, on the fourth day.

Sarcoma.—In turning to sarcoma we find the curative action of the erysipelas even more marked, Of the 19 cases of sarcoma we find eight, or forty-two per cent., well and free from recurrence from one to seven years after the attack of erysipelas. Nearly all of these 7 cases have a remarkable history. The case of Dr. Bull and Dr. Gerster, and two of my own have already been described.

The remaining 4 were as follows: The first (Biedert's) was a very large round-celled sarcoma, involving mouth, face, nose, and orbit of a child ten years of age. The features were greatly distorted, and the general condition so bad that death from exhaustion was anticipated soon. While in daily expectation of being obliged to do a tracheotomy, a severe attack of facial erysipelas occurred. The tumor disappeared, as if by magic, during the course of the erysipelas. The child recovered, and at the end of a year was perfectly well, with no indication whatever of a recurrence.

The next case (Bruns') was a melanotic sarcoma of the breast, with entire disappearance and no recurrence.

The sixth case (Busch's) was a multiple sarcoma of the face that entirely disappeared after an attack of facial erysipelas, and did not return.

The seventh case (Klechlatt's) was a lympho-sarcoma of the neck, very large; the erysipelas in this case being the result of inoculation.

In addition to these seven cases there is one other, a probable sarcoma of the breast, that was cured. Ten of the remaining eleven showed more or less marked improvement; in some cases the tumor entirely disappearing, and not recurring for several months. One case died as a probable result of the erysipelas, which was in this instance accidental, and a second died from inoculation.

These cases have been in no way selected, and I have made every effort to include all cases resting upon competent authority; yet it might be urged as an objection to accepting these figures as representing the true percentage of cures, that cases have probably occurred which, owing to no marked improvement following the erysipelas, naturally failed to be reported. This objection, though valid as far as the accidental cases are concerned, would cease to hold in the cases of inoculation for the reason that, being so few in number, all, or nearly all, have probably been reported.

Grouping by themselves, then, the cases where the erysipelas was artificially produced, we find 7 cases of carcinoma, 1 cure, or 14.3 per cent., and 8 cases of sarcoma, 3 cures, thirty-seven per cent. These cases were as follows: Fehleisen, 2; Kleeblatt, 2; Busch, 1; the remaining 3 cases being my own.

These figures may then be taken to fairly represent the curative effect upon carcinoma and sarcoma in the worst cases; and when we reflect that in nearly every instance the tumor was not a primary growth, amenable to operative treatment, but either a recurrence after operation had been tried and failed, or from its nature inoperable, then, and then only, are we in a position to fully estimate the importance and value of erysipelas as a *curative* agent.

In a former paper (vid. supra) I referred briefly to the different theories offered in explanation of this benign action, and even then I was inclined to believe it due to "antagonistic bacterial action," the neoplasm being regarded as dependent upon some unknown micro-organism.

Since that time the evidence in favor of the micro-parasitic origin of cancer has been steadily and rapidly accumulating until, at the present moment it amounts to almost an absolute demonstration. Time will not permit more than a brief mention of the more salient points of this evidence, yet since a proper appreciation of its character and strength is necessary to anything like a clear understanding of the probable action of erysipelas upon malignant tumors, we cannot pass over it unnoticed. We shall consider:

1. *The Close Resemblance of Cancer to other Diseases known to be of Bacterial Origin.*—The striking analogy between cancer and tuberculosis was noticed long before the tubercle bacillus was discovered. Sir John Simon in 1877, clearly pointed out this analogy, and in fact even then argued very strongly in favor of a micro-parasitic origin of cancer. His paper states the points at issue so clearly and briefly, and moreover the facts adduced and the conclusions drawn—showing as they do an almost prophetic insight—make it a paper that can be read with the greatest interest and profit to-day. He pointed out the error in the earlier investigations in allowing the "anatomical forms," interesting enough in themselves, to obscure the more important "property of infectiousness," which he regarded as the "real puzzle" of the disease. "The anatomical forms are matters of mere local accident, but the infectiousness of cancer represents its very cause." He showed that the element of heredity plays an entirely different *rôle* in cancerous and non-cancerous tumors; that while in the latter the hereditary influence often seems to be the *entire* cause of the tumor—an "embryonic fault" belonging to the same pathological class as supernumerary toes and fingers,—in *cancer* it supplies only that portion of the cause which, as in tuberculosis, is familiarly known as *predisposing conditions*. This opinion we know is generally accepted at the present day. There is, moreover, a growing tendency to no longer adhere to the stereotyped classification of tumors, and we venture to predict that in the near future, instead of "tumors," a class at present embracing elements without the remotest analogy, either in their etiology or mode of development, we shall have two main groups—the first of which might be designated as *congenital hypertrophies*; the second, *neoplasms*, etiologically dependent upon infection from without.

This statement may seem a trifle strong, since Cohnheim's embryonic theory of the origin of cancer is not only still held by the larger body of medical men, but has quite recently been maintained by Baumgarten in Germany as well as by distinguished pathologists in this country. In spite of all the objections and criticisms, the micro-parasitic theory has steadily gained ground, and just now the confirmations are rapidly outnumbering the objections. These objections, the most of which were formulated by Cohnheim himself, ten years ago, have nearly all been answered. He argued that cancer could not be of microbic origin, first, because it was neither epidemic nor endemic. Tuberculosis is neither epidemic nor endemic, yet is due to Koch's bacillus. Malaria is neither contagious nor epidemic, yet is caused by an intra-cellular parasite; again, tetanus is not contagious, and hardly more endemic than cancer itself, as shown by the researches of Haviland, and confirmed by recent investigations.* The second objection was, that cancer could not be inoculated from one individual to another or to animals.

Cancer has been transferred from one part of the body to others in the same individual (Hahn and Von Bergmann) by inoculation, and moreover, it has been transferred from one animal to others in a few cases. That most of the experiments in inoculating animals have failed is really no objection to the theory. We know that there are many vegetable and animal parasites whose life history embraces a long cycle of changes in form and development, only a brief portion of which is found in the "host."

The *evolution* of *parasites* is a subject of great interest and importance, yet one that, as yet, has been but little investigated by the trained naturalist and biologist.

For a clear understanding of the "laws of parasitism," and their relation to specific diseases, we are much indebted to the recent and valuable contribution of Dr. Joseph Frank Payne, of London. If his view, that there is a definite relation between the contagiosity of a specific disease and its chronicity, be correct, we at once see a striking analogy between cancer on the one hand, and leprosy and tuberculosis on the other, and there is no need to go further for an explanation of the slight contagiosity of cancer. Ballance and Shattuck go so far as to assert that "there is no fact in the etiology or life history of carcinoma or sarcoma that has not its counterpart in tuberculosis."

2. *Analogous Diseases in Animals and Plants known to be of Parasitic Origin.*—In the vegetable kingdom we find a large variety of "tumors" known as "galls." One by one these have all been proven to be of parasitic origin. If we turn to the lower animals, we find in "coccidial infection" an analogy so striking, that many observers have considered it identical with cancer. Without entering into any discussion of this question, this much may be regarded as proven: That certain low organisms or protozoa known as coccidia, have been found in animals, chiefly rabbits; that they possess the very *rare* property of being able to set up a proliferation of epithelium; that in the animals in question, and at least in one case (Leuckhart's), if not in two cases in man, they have produced multiple tumors associated with the same clinical symptoms and pathological changes that are found in true cancer.

We must further admit that several independent observers, notably Sawtschenko on the Continent, and Ruffer and Walker in England, by the use of improved methods of staining, have been able to demonstrate the constant presence of protozoa in a very large number of specimens of carcinoma. That these are true parasites and not "invaginated cells" or "degenerated metamorphoses," as many have been inclined to regard them, has been very recently confirmed by the testimony of Metschnikoff, the highest living authority in micro-zoölogy.

These protozoa are so similar to the coccidia already referred to, that they can scarcely be differentiated. Whether or not they are identical, seems to me a matter of indifference; that they are very closely allied forms seems more than probable. That they have not yet been cultivated outside the body is no evidence against their

* The researches of Gueilliot prove cancer to be mildly contagious.

being the cause of cancer, when we consider how much time it has taken to discover their mere presence.

If, with a distinguished authority, we admit that "for the development of cancer it is necessary that there should be a continuous irritation, and one capable of multiplication," and knowing as we do that the irritants capable of fulfilling these conditions are limited almost entirely to the animal and vegetable parasites, we can scarcely fail to accept the micro-parasitic theory. The great merit of this theory, as Ballance and Shattuck have pointed out, is that "it not only offers a working hypothesis for further investigation with which none other can compare, but it holds out the hope that it may one day admit of scientific treatment based on the same lines as other micro-parasitic diseases." Having endeavored to make clear the grounds for believing in the parasitic origin of cancer, the explanation of the action of erysipelas is not difficult. If a small quantity of blood-serum of an animal rendered immune to tetanus is capable of destroying or rendering inert the virulent bacilli in a fresh case, it is quite as easy to understand that the toxic products of the erysipelas streptococci might bring about such changes in the blood-serum as to destroy the parasite of cancer. The parasite having been destroyed, the irritation would consequently cease, and this would lessen the hyperæmia of the parts, upon which factor the life of the tumor-cells of low vitality largely depends.

This theory, if it may be called such, has occurred to me as offering the best explanation of all the phenomena observed. It explains the rapid degeneration, with a breaking down of the tumor tissue, as well as the slower disappearance by absorption. It also explains those interesting cases, several in number, where an erysipelas remote from the tumor has caused a disappearance in precisely the same way as a local attack. These latter cases, it would seem, prove the phagocytosis theory insufficient to explain the action of erysipelas. It is worthy of note that the action of erysipelas upon lupus and the secondary and tertiary lesions of syphilis (see Mauriac) is similar to that in malignant tumors, and this fact, joined to the fact that erysipelas has never been known to affect non-malignant tumors, is another point in favor of the parasitic origin of cancer. The attempt to explain its action on the theory of a mere local irritation, classing it with the various caustics, needs only to be mentioned to be disproved.

The clinical facts already mentioned, that a number of malignant tumors have disappeared as a result of an erysipelas in another region of the body, coupled with the very recent experiments of Professor Spronck and his co-workers, settle the point beyond dispute.

Dangers Associated with Erysipelas.—I have endeavored to ascertain as far as possible the actual mortality of uncomplicated erysipelas. Nearly everything that has been written upon the subject is of little value in determining this point, because the term "erysipelas" has been used in a very loose way, including many cases of cellulitis and septic infection. I do not believe in the identity of the streptococcus of erysipelas and the streptococcus pyogenes, although I am aware that the opposite opinion is held by many of the leading bacteriologists. Those who hold to the identity of the two germs, base their opinion largely upon the close resemblance, morphologically and biologically, and they claim that the clinical differences are due to the different sites of infection and variations in virulence of cultures; that the same germ in the outer layers of the skin will produce true erysipelas; that injected deeply into the tissues it will cause cellulitis and multiple abscesses. I believe this explanation to be entirely theoretical and not supported by facts. During the course of these experiments I have injected, upward of one hundred and fifty times, pure cultures of the streptococcus of erysipelas, of almost every degree of virulence, into the (human) tissues, superficially and deeply. In but two cases did I see an abscess, and in one of them a careful bacteriological examination was made of the pus (before it had become contaminated), and mixed cultures were found, the staphylococcus aureus being present with the streptococcus.

There appears to be good ground for believing that when suppurative processes are associated with erysipelas, a mixed infection is present, and that there is a real and important difference between the germ of erysipelas and the streptococcus pyogenes, in spite of their close resemblance. The fact that they are pathogenic for different animals respectively, and also their different action with reference to lactic acid, are other points against their identity.

The most elaborate, as well as the most recent, investigations on the subject of the identity of the streptococcus of erysipelas and the streptococcus pyogenes, were made by Professor Cruikshank and reported at the last International Congress of Hygiene and Demography (1892, vol. ii., sec. ii.). The results of these investigations were against the identity of the germs.

If we include the cases of diphtheria inoculated with erysipelas (Babtschinski), we have a total of forty cases where erysipelas has been artificially produced, with but two deaths—five per cent. We know that the virulence of the germ varies within wide limits, and that it can be modified at will by passing it through animals; therefore it seems reasonable to assume that with proper precautions its mortality in inoculation can be made trifling or *nil*.

Conclusions.—1. The curative effect of erysipelas upon malignant tumors is an established fact. 2. The action upon sarcoma is more powerful than upon carcinoma. 3. The treatment of inoperable malignant tumors by repeated inoculations of erysipelas is both practicable and not attended with great risk. 4. The curative action is systemic as well as local, and probably due chiefly to the toxic products of the streptococcus, which products may be isolated and used without producing erysipelas. 5. This method should *not be employed indiscriminately* until further experiments have proved its limitations.

SAW PALMETTO. This palm, *Serenoa serrulata*, forms the common palmetto scrub of South Carolina, Georgia, and Florida. The whole plant has marked demulcent and nutritive properties, and is extensively used as a local remedial agent in all forms of disease of the mucous membranes, especially when associated with debility and wasting. Its use is followed by an improved digestion, increased strength and flesh, and a soothing influence on any irritable state of the membranes. It is used in catarrh, ozæna, and bronchitis, and has a special value in diseases of the bladder and reproductive organs. Reginald Harrison has found it very beneficial in irritable states of the bladder, and compares its action to pareira. It is also reported to be of benefit in affections of the prostate gland. Another property that is claimed for it is its vitalizing and strengthening action upon weakened and wasted glands of the generative organs. It is said to cause a rapid development of the mammæ, ovaries, and testes, when these organs are debilitated as the result of masturbation and sexual excessess of all kinds.

The fluid extract of the seeds is the most convenient form for administering the drug; it is given in half to one drachm doses, repeated three or four times a day.

Beaumont Small.

SCOLIOSIS. No new facts as to the pathology and etiology of scoliosis have recently been advanced, though the writer has observed cases that clinically present all the symptoms of tubercular spondylitis, except the posterior knuckle of that disease, and in their course are quite unlike the ordinary cases of scoliosis. It being now recognized that one of the earliest symptoms of spondylitis is a lateral curvature of the spine, and this lateral curvature, if sufficiently severe and prolonged, presents the same evidences of rotation of the vertebræ that are found in scoliosis, it has been suggested that some cases of scoliosis may be truly cases of the dry form of spinal caries in which the lateral deformity has obscured the usual long, rounded posterior curvature. The treatment to which these cases have been subjected appears to confirm this view, that is to say, they have grown steadily worse under manipulations and exercises, and steadily better under immobilization. Be this as it may, the observation has an important bearing upon treatment, a point to which reference will again be made.

In advanced cases of scoliosis the deformity is so entirely different from the usual deformity of Pott's disease, that there will be no difficulty in making the diagnosis; but in cases of slight deformity such is not the case, and without observing the patient for some time, or noting the results of treatment, it may not be possible to differentiate. The primary curve of scoliosis is usually first noticed in girls at about the age of puberty; it is, as a rule, located in the mid-dorsal region with the convexity to the right. The lateral deviation of commencing spondylitis is quite as often found in younger children, in boys, with convexity to the left and in any portion of the spine.

Potts' disease is often accompanied by distant pain; scoliosis never is, except in old and very great deformities. In Pott's disease the patient often moves and bends with anxious care; in scoliosis this is wanting. But the chief diagnostic point is the rigidity of the curvature. In Pott's disease the curve is rigid from its very beginning and to motion in all directions; in scoliosis it is not at all rigid for some time, and then only in the direction of diminishing the curvature: and not until true synostosis has taken place in the concave side is it rigid to bending in all directions. Forcible manipulations to correct the curvature, and exercises, increase the rigidity and the deformity in Pott's disease, but reduce both rigidity and deformity in scoliosis.

Treatment.—At the present time there are three well-defined plans of treatment, namely, by exercise alone; by exercise and some form of removable retention cor set or brace; and by forced correction of the deformity and retention by permanent plaster jacket, to be followed subsequently by a removable corset and exercise, and ultimately by exercise alone.

The most well known method of treatment by exercise alone is that of the Ling system of Swedish gymnastics. This we will not describe, inasmuch as we believe it has been improved upon by Mr. Bernard Roth, of London. The key-note of Mr. Roth's work is that he puts the patient in such posture as will most perfectly correct the deformity, and in that posture exercises him. Many of the exercises are conducted while the patient is recumbent, the best posture at first being during recumbency. The exercises are administered daily for three months, the patient then continues them at home for three months; again they are administered by the surgeon for two months, and then at home for six months; then by the surgeon for one month, and finally at home for one year, when the final examination and record is made. Roth does not expect to correct any osseous change, and only claims to make the patient hold himself habitually in that best posture which he can maintain for a few minutes at the first examination.

The exercises are as follows:

1. Lying on back; arms by the sides of the body; palms upward; slow, deep inspiration by the nose; slow expiration by the mouth. (Repeated four times.)
2. Similar exercises with the arms extended by the sides of the head. (Repeated four times.)
3. Same position as 1; head rotation on axis to right and left alternately. (Repeated four times.)
4. Lying on back; simultaneous circumduction of both shoulder-joints from before backward; elbows and wrists kept extended. (Repeated twelve times.)
5. Lying on back; one hip circumduction both ways; knee kept extended. (Repeated ten times.)
6. Lying on back; simultaneous extension of arms upward, outward, and downward, from a position with the elbows flexed and close to the trunk. (Repeated four times.)
7. Lying forward; one hip circumduction both ways; knee kept extended. (Repeated ten times.)
8. Sitting on couch, with back at an angle of forty-five degrees; ankle circumduction down, in, up, and out, while the toes are directed inward the whole time. (Repeated twenty times.) Also foot adduction, patient resisting, abduction, surgeon resisting. (Repeated eight times.) (For flat-foot.)
9. Lying on back; with arms extended upward by the sides of the head; flexion of both arms, surgeon resisting by grasping the hands, followed by extension, patient resisting. (Repeated six to eight times.) (The patient's knees flexed over the end of the table, fix his trunk.)
10. Patient astride a narrow table or chair without back, with arms down and hands supinated; trunk flexion at lumbar vertebræ, patient resisting slightly, fol-

lowed by trunk extension, surgeon resisting by his hand against the back of patient's head. (Repeated six to eight times.)

11. Patient, with arms extended upward, stands with head, back, and heels against a vertical post with pegs on each side, which he grasps. The surgeon gently pulls the patient's pelvis forward by his hands on the sacrum, patient resisting; and then the patient moves back the pelvis to the post, surgeon resisting. At no time are the patient's heels to be raised from the floor. Also pelvis rotation on its axis to right and left alternately, surgeon resisting with his hands on each side of pelvis. (Repeated six to eight times.)

12. Lying on back, with head and neck projecting beyond the end of the table; arms by the sides of the body, palms up; the head is gently flexed by the surgeon's hand on the occiput; patient resisting, followed by head extension, surgeon resisting. (Repeated eight times.)

The second plan of treatment aims to constantly maintain the best possible posture, by aid of some removable corset or brace, and at the same time to develop the muscular system by exercises. Moderately severe cases ultimately lay aside the support, but the inveterate deformities must be supported a very long time. The most readily applied support is the plaster-of-Paris corset. It is applied in the same manner as the ordinary plaster jacket, but before fully setting is cut down the front, sprung off, and after being trimmed out, covered, and supplied with laces, is applied to the patient, who is partially suspended as in the original application of the jacket. A well-made plaster corset will last from two to six months.

For the sake of having a more durable corset various substances have been employed. Three only merit description: The leather corset as made by Dr. A. J. Steele, of St. Louis; the Waltuck wood corset as made by Dr. A. M. Phelps, of New York; and the paper corset as made by Dr. L. A. Weigl, of Rochester. In making either of these corsets a plaster jacket is first made upon the patient partially suspended. This jacket is filled with plaster-of-Paris cream, which sets to form a cast of the patient. Upon this cast the corset is constructed.

The Leather Corset is made from a kind of leather, undressed with oil, known as saddle skirting. It is soaked in water until quite soft, wrapped around the plaster mould, and wound with a small, strong rope. This rope must be wound very snugly, and for this a specially devised machine is necessary. It is quite impossible to draw the rope by hand sufficiently tight to force the leather into place. The whole is then subjected to a baking process to harden the leather. The heat used must not be too extreme, or the leather will become brittle. It is then bored with small holes, lined with kid, and supplied with hooks for lacing.

The Wood Corset, devised by Dr. Joseph Waltuck, of Odessa, Russia, and introduced into this country by Dr. A. M. Phelps, of New York, is made as follows:

Suspend the patient after the tight-fitting shirt has been applied. Indicate with the blue pencil marks around the body on the shirt, the length of the corset desired. Apply the plaster-of-Paris bandages as in making an ordinary plaster-of-Paris corset. When the plaster is set, remove it from the body by cutting it down in the front. Strip out the shirt from the corset, when the blue pencil marks will be seen on the inside of the plaster corset.

A few turns of the plaster bandage around the plaster corset are necessary. Put in a large dish a quantity of oakum picked up finely. Mix with this a quantity of plaster-of-Paris. After having greased the inside of the corset with vaseline, stir water into the plaster-of-Paris and oakum until it is of the consistency of thick mud. Apply this over the inside of the corset to the thickness of three inches. After it is set remove the corset, and a perfect cast of the body will be the result. The blue line will be transferred from the plaster mould to the cast. The oakum is put in the plaster to facilitate the modelling, and also to make the cast tough, because

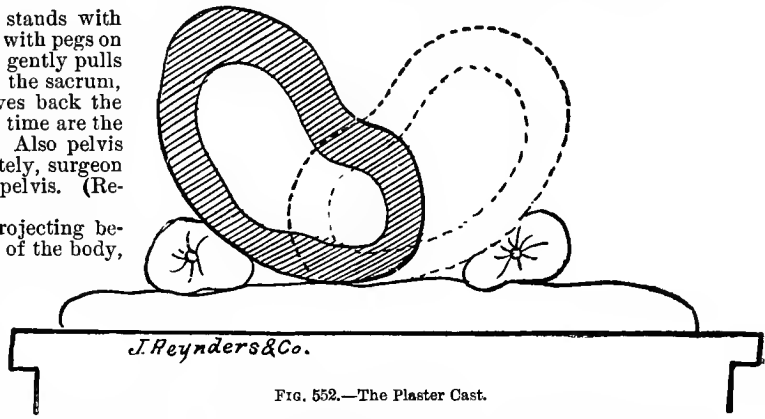

Fig. 552.—The Plaster Cast.

considerable hammering has to be done upon it. The cast should dry two or three days in a temperature not

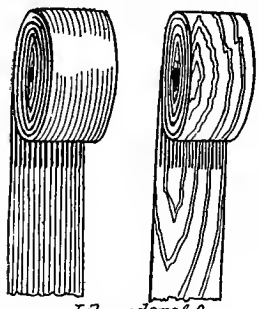

Fig. 553.—Proper Grain.

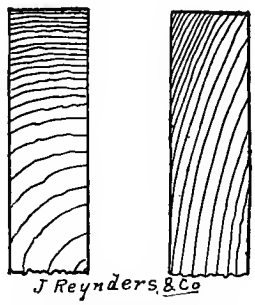

Fig. 554.—Imperfect Grain.

exceeding one hundred and fifty degrees. Any imperfection in the cast should be remedied with plaster-of-Paris, building out such points over the breast and hips

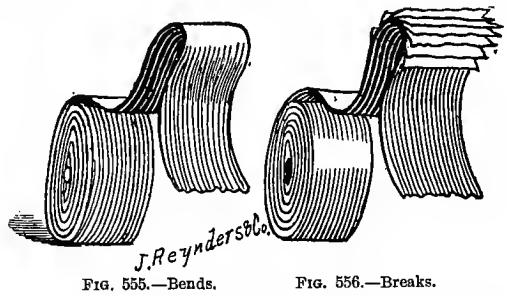

Fig. 555.—Bends.

Fig. 556.—Breaks.

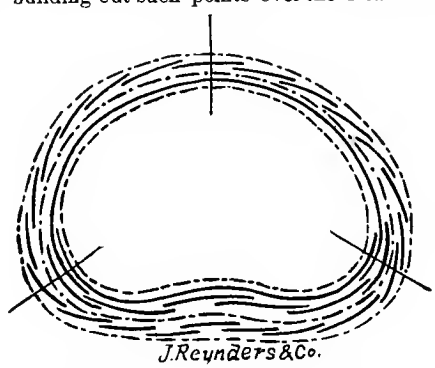

Fig. 557.—Shows Layers of Wood and Linen.

and deformed portions as may seem necessary to make an artistic corset. Cover the cast with raw linen which has been wet for the purpose. Some difficulty will be experienced unless the workman has seen the work done. The cast is placed on a table with the sandbags, as seen in Fig. 552.

The wood from which the corset is made is taken from the edge of a plank the grain of which is as seen in Fig. 553. Fig. 554 shows imperfect grain. The grain running as in Fig. 553 makes a tough strip that will bend as seen in Fig. 555. When the grain runs as in Fig. 554 and the wood is bent, it will present the appearance of Fig. 556, which has an element of weakness.

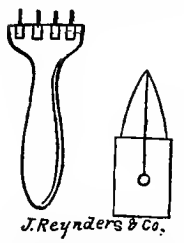

Fig. 558.—Tool for Splitting Wood, and Pincers Used in Construction of the Corset.

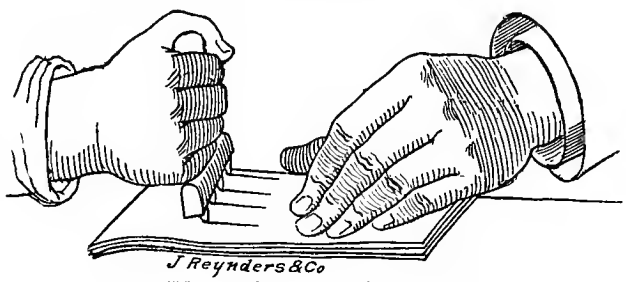

Fig. 559.—Splitting Several Thicknesses at Once.

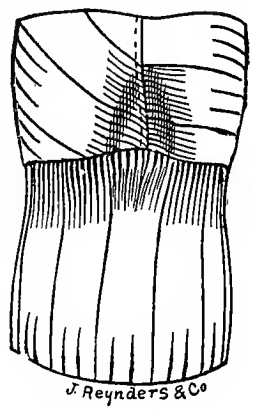

Fig. 560.

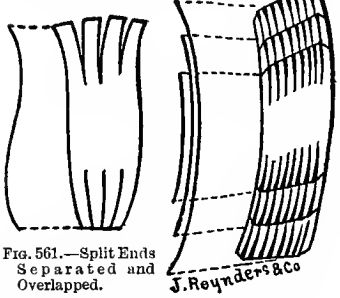

Fig. 561.—Split Ends Separated and Overlapped.

The layers of wood and linen are explained in Fig. 557, the dotted lines being linen, the black lines wood, and it will be seen that there are three layers of linen and two of wood in the front of the corset, with three layers of linen and three layers of wood in the back and side.

Over the hips extra pieces are put in, making it even thicker, which will be explained later.

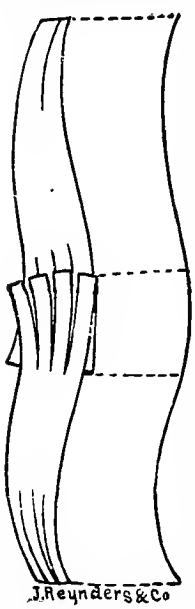

Fig. 562.—Spreading and Lapping Split Ends.

The cast is now laid with the back up. Draw three longitudinal lines, one in the centre in front, and one on each side, dividing the cast in three equal parts. Cut several strips of wood in length long enough to overlap the lateral lines two inches.

With the tool, Fig. 558, split the ends of the wood as seen in Fig. 559. The object of this is to allow the ends of the wood to spread or to overlap, so as to fit all inequalities, as seen in Figs. 561, 562, 563, 564, and 565. Prepare the glue by soaking it in water over night, then melt it. To a pot (holding one quart) of glue, add one tablespoonful of glycerine. Dip the glue-brush into the glue, wiping it as dry as possible on the edge of the pot, so as to use the least possible quantity.

A strip of wood is covered with glue, and the brush drawn along the part of the cast where the wood is to be laid, beginning at the top of the cast with a transverse layer; strip after strip is applied, and overlapping the strip above one-eighth of an inch. Cover this layer of wood with the linen and glue, and hammer the whole together. Turn the cast on the side, and working from the centre in front, put the strips on horizontally, overlapping the strips already on two inches. Cover this with linen, lapping on the back two inches. Finish the opposite side in the same manner.

Beginning in the back, put on the strips longitudinally, overlapping four inches in the centre of the cast from the top and bottom. Left side.

Hammer the wood well together with an ordinary shoemaker's hammer. Now stay the corset with wood over the hips, and also strengthen the corset by putting on another layer of wood diagonally from the shoulder to the opposite hip, meeting at a point in the centre of the waist. Cover the entire work with linen, putting the least amount of glue on the wood before the linen is applied. After twenty-four hours the corset can be removed from the cast, fitted to the patient, and sent to the trimmer, who will treat it in the following manner. Corsets made according to the method followed at the time I observed the process, were not as perfect as they should be.

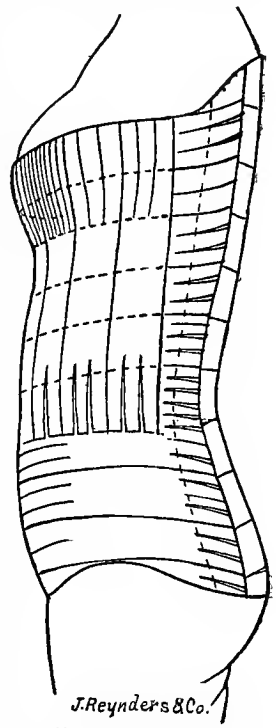

Fig. 563.—Showing the Relation of the Horizontal and Vertical Layers.

1. The slightest excess of glue moistened by the perspiration of the body coming in contact with the shirt or the skin, was exceedingly disagreeable. 2. The perforations in this corset weakened it, and allowed the glue to exude during perspiration.

To obviate all this, the corset has been perforated, as seen in Fig. 568, in which perforation eyelets are punched. A special machine facilitates the perforating and the punching of the eyelets. The lacings are stitched on as in Fig. 568. Trim the top and bottom with kid. The entire corset is shellacked inside and outside with two or three coats of shellac, which renders it impervious to moisture, the eyelets ventilating it perfectly.

Weigl's Paper Corset.—The corset is constructed of paper and linen, on a cast of the patient's trunk which is obtained in the usual way. The cast should be as smooth as possible, and may be either solid or hollow.

The paper employed is known as pulp paper, such as is used for obtaining the matrix for stereotyping forms in newspaper offices.

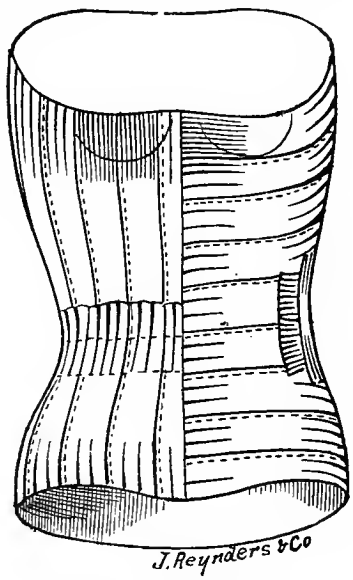

FIG. 564.—Showing Manner in which Layers are Lapped and Waist Strengthened.

The proper manipulation of the paper is an essential feature. It should be saturated with water and the excess removed by placing it between towels or cloths. It is then cut in strips of suitable width and length, according to the size of the jacket to be made. The details in making the jacket are substantially the same as those of the wood corset, Fig. 567, the difference being in the material used and the method of finishing.

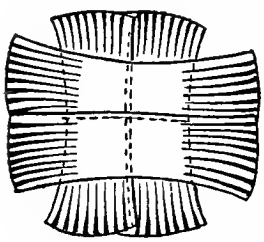

FIG. 565. — Arrangement for Strengthening Corset over Hips.

The various steps are as follows: A piece of the linen thoroughly dampened is smoothly stretched on the

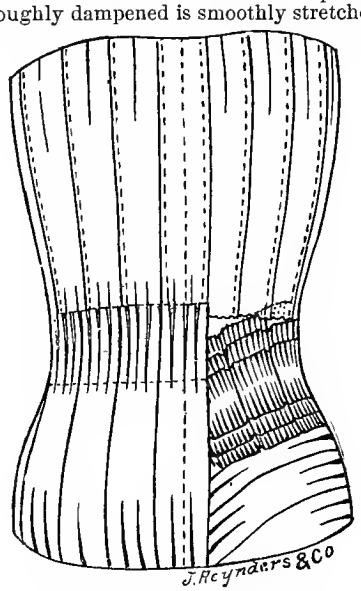

FIG. 566.—Rear View of Fig. 564.

cast and secured by tacking it along a line drawn in the centre of the cast, in front and around the top and bottom of the cast. In subjects with well-developed breasts and hips, the application of the linen will be much facilitated

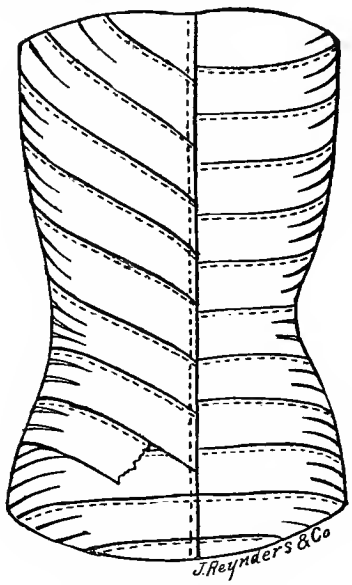

FIG. 567.—Showing Oblique Layers.

by approximately fitting it to the cast by sewing seams of proper shape along the axillary lines, after the manner of fitting dress waists to the form. The first layer of paper is now pasted on this foundation, in vertical strips, the strips overlapping each other about three-eighths of an

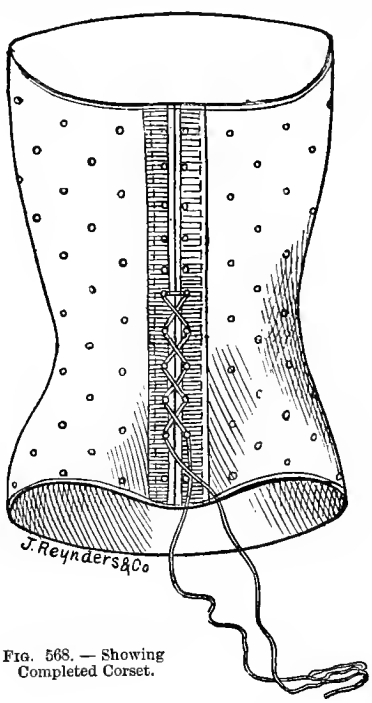

FIG. 568. — Showing Completed Corset.

inch. The paste most suitable is that known as Boston steam paste, such as is used by paper-hangers, bill-posters, etc. The second layer of paper is applied horizontally. Next a layer of linen is put on, which may be in strips

of any width. Two layers of paper strips are now applied obliquely, followed by another layer of linen, and finally two more of paper, one horizontal and the last vertical. If desired, a layer of linen may be put on as a finish, but it is not essential. Any individual points may be strengthened by applying short strips crossing each other, or built up like a wagon spring. The jacket is allowed to dry thoroughly on the cast before removing it. This secures freedom from warping. The drying may be hastened by resorting to artificial heat, as the jacket is unaffected by even a high temperature. When dry the jacket is removed from the cast by taking out the tacks which secured the first layer of linen, and trimmed as may be necessary. It is then perforated by a drive-punch. To render the corset thoroughly waterproof, it is enamelled inside and outside with about two coats of Devoe's white enamel paint, applied with an ordinary flat brush. When this is thoroughly dry and hard, the edges are bound with soft leather, alum-tanned sheep skin being the best. The easiest way to bind the corset is to glue the leather on with a liquid glue. The straps with lacing hooks are sewed on. Shoulder straps, steel strips, head-rests, etc., may be readily riveted to the jacket.

Forcible Correction and Permanent Retention. — The third plan of treatment, that of forcibly correcting the deformity and retaining the correction by a permanent plaster jacket, owes its recent development to Hoffa, of Würzburg, and Bradford, of Boston. The apparatus illustrated in Figs. 569 and 570 is Bradford's modification of Schede's apparatus for forcible correction, and is used as an exercise for stretching the shortened parts, or as a means for gaining an improved posture preliminary to the application of a permanent plaster jacket. The appliance is a standing frame made of steel rods. The whole is furnished with arrangements for vertical traction, for fixation of the pelvis and shoulders, and for direct screw pressure upon any part of the thorax which may project abnormally.

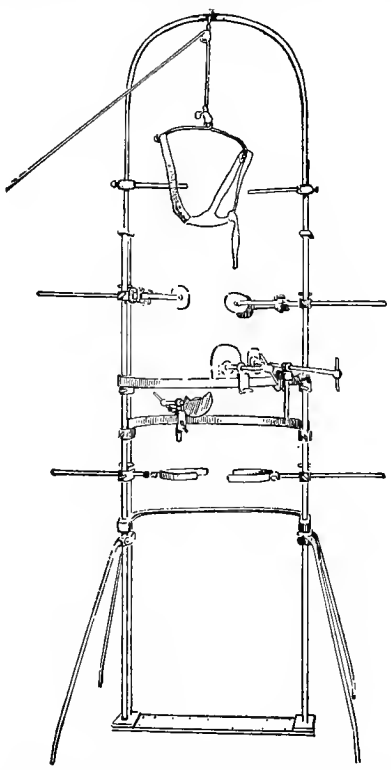

FIG. 569.—Bradford's Modification of Schede's Apparatus.

The frame is eight feet high and three feet wide, and consists of two side pieces, six feet high, connected above by an arched rod of steel, and below by a flat plate which serves as a standing basis. Each side is formed of two parallel rods, three-quarters of an inch in diameter and four inches apart, firmly secured to each other above and below. Upon these two parallel rods run blocks of steel,

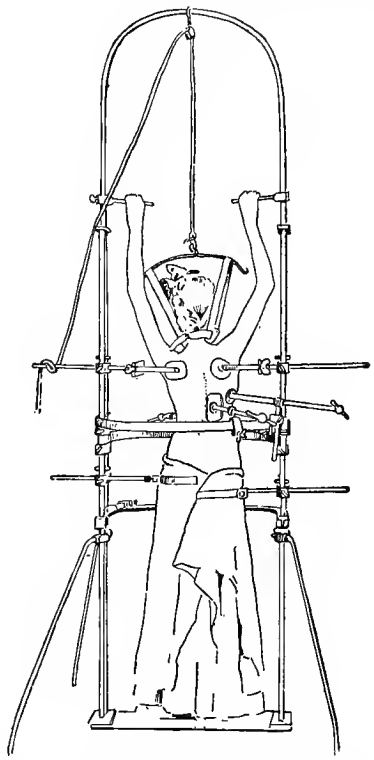

FIG. 570.—The Same Apparatus, with Patient in Position.

which may be set at any height by means of a thumb-screw. The lower of these on either side is perforated for a sliding, horizontal, square bar of steel, one-half an inch in diameter, on the inner extremity of which are fastened two curved pieces of steel, so arranged as to firmly grasp the pelvis. The upper block on either side is also perforated by a horizontal steel bar, and to this is fastened an attachment giving pressure on the shoulders in front and behind. These blocks, bars, and fixation-plates slide smoothly and can be fixed as may be required to hold the pelvis and shoulders securely.

The steel bars which carry the pressure-screws together form a half-circle, one in front and one behind, both together encircling the patient. These are attached at the sides to sliding steel blocks, and can be set at any height which is desired. The anterior bar is secured firmly at both sides; the posterior is hinged upon one side, and is then so arranged that it can be swung open in order that the patient may be put into the machine, and then be swung back and secured by a clamp to the steel block upon the other side. On the semicircular bars slide small steel blocks which can be secured at any point. Each of these blocks carries (at right angles to the bar) a rod cut with a screw-thread. At the inner end of each rod is a flat plate (made to play freely within a small arc) and at the outer end is a handle. Twisting the screw-rod regulates the pressure, which can be adjusted to any desired point by shifting the blocks. It would at first seem that it was impossible to place a plaster jacket on a patient whose thorax has been corrected by forcible pressure. It will be found, however, that if this is done with care, the pressure being increased gradually, a marked improvement in the distortion of the

thorax may be made. The patient should be placed in as nearly the corrected position as possible by means of the appliance already described, and the plaster jacket applied in the usual way, except that the bandages are wound about the trunk, avoiding the screw-pressure rods. The patient's skin is protected under the points of pressure by pieces of saddlers' felt, and even pressure is secured by thin steel plates which are incorporated in the bandages. The plaster corset is worn for a week or a fortnight, when another can be applied in a similar way with a slight increase of pressure, if practicable. It is, of course, possible to apply enough pressure to render the jacket unendurable; but short of this, it will be found that a substantial amount of pressure can be borne without more discomfort than that attending any jacket. If the jacket is split and removed the amount of correcting pressure is diminished, even though the split jacket be well laced afterward. If the greatest amount of correction is sought for persistently, the fixed bandage is to be preferred.

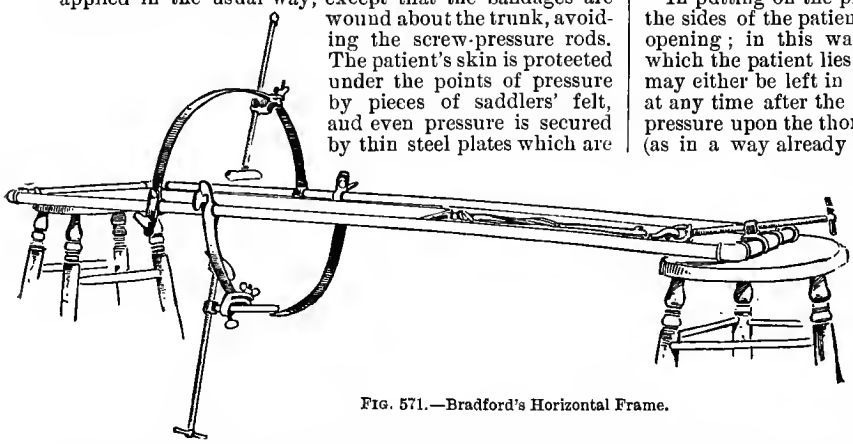

FIG. 571.—Bradford's Horizontal Frame.

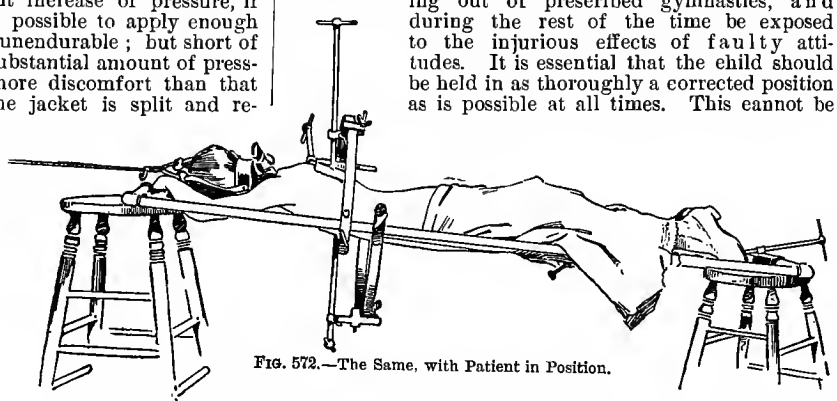

FIG. 572.—The Same, with Patient in Position.

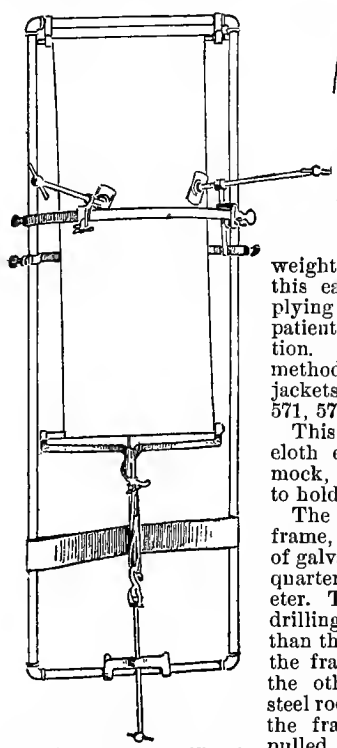

FIG. 573.—The Same, Viewed from Above.

A certain amount of discomfort is experienced by a patient who is suspended so as to entirely remove the super-incumbent weight. In many instances this can be avoided by applying the jacket with the patient in a recumbent position. For this a modification method for applying plaster jackets can be used. (Figs. 571, 572, and 573.)

This consists of a sheet of cloth constituting the hammock, and a frame arranged to hold the cloth taut.

The frame is an oblong frame, six feet by two, made of galvanized iron pipe, three-quarters of an inch in diameter. The cloth is stout sheet-drilling, somewhat wider than the patient, folded over the frame at one end, and at the other stretched over a steel rod which reaches across the frame. If this rod is pulled upon strongly, the sheet is kept tight, and sagging so prevented. This is done by connecting the rod by means of a cord to a screw staple fastened to the other end of the frame. Screwing the rods regulates the tension.

In putting on the plaster jackets, the cloth is cut along the sides of the patient, and the rolls passed through the opening; in this way the part of the hammock upon which the patient lies is incorporated in the jacket, which may either be left in permanently or may be withdrawn at any time after the jacket is hard. To secure direct pressure upon the thorax, the screw force can be adjusted (as in a way already described), and semicircular bands of steel adjusted on the upper and on the under side of the frame. (Fig. 573.)

This appliance can also, like the other, be used as a means of daily exercise. Actual experience has shown that the curved spinal column can be straightened in this way as much as by vertical suspension, and with much less discomfort to the patient. In the thorough treatment of severe lateral curvature the patient should be under treatment continuously, that is to say, it is not sufficient for the patient to devote an hour or more a day to the carrying out of prescribed gymnastics, and during the rest of the time be exposed to the injurious effects of faulty attitudes. It is essential that the child should be held in as thoroughly a corrected position as is possible at all times. This cannot be done by purely muscular exertion, for when muscular fatigue comes the faulty attitudes are liable to be resumed. Even in recumbency children often take faulty positions.

The objects of treatment are first to increase flexibility of the parts of the spine where flexibility is abnormally limited; secondly, to secure the maintenance of an improved attitude by the use of the retention apparatus, until the improved attitude has, by the alteration in the structure of the tissues, become habitual.

Forced correction and the permanent jacket should always be followed by a removable jacket, or corset, and exercise; and this by exercises alone; and the patient should be under observation for some years, at least until the full stature has been attained. Anything short of this is quite sure to be attended by a relapse.

John Ridlon.

SCOPOLAMINE. A new alkaloid, which is attracting attention on account of its chemical and therapeutic resemblance to hyoscine, hyosciamine, and atropine. It may be obtained in small amounts from plants of the order *Solanaceæ*, such as henbane, duboisia, stramonium, and belladonna, but its chief source is *Scopolia carniolica* Jac. (*Scopolia atropoides*). This plant, named after Scopoli, an Austrian naturalist of the last century, is a perennial spring-flowering plant, with dull, purple flowers, closely allied to hyosciamus niger. The flowers are solitary, placed on axillary pendulous stalks, arising from the axils of the leaves which are in pairs, one being larger than the other. Corolla. funnel-shaped, tra-

versed by fifteen nerves, the limbs divided into five very short lobes; stamens equal in length, the filaments short, dilated and hairy at the base, cylindrical above; ovary surrounded by a five-lobed fleshy disk; fruit similar to that of the henbane. The rhizome is very similar to the belladonna root, both in appearance and structure; it was introduced as a cheap substitute for belladonna root and called belladonna scopola. It is a native of the mountainous districts of Austria and Hungary, where it grows plentifully in a wild state. *Scopolia Japonica* is another species which grows in Japan and is known as Japanese belladonna. This plant is less known than the European plant, but its constituents are the same.

Scopolamine has been fully studied by Professor Ernest Schmidt (*Druggists' Circular*, December, 1892), in connection with his researches upon the composition of the various alkaloids common to the members of the night-shade family. The conclusion that he arrives at is that scopolamine and hyoscine are identical alkaloids, or rather, that the hyoscine of commerce is really scopolamine, with the chemical formula $C_{17}H_{21}NO_4$. The alkaloid grows in large, transparent crystals, containing one molecule of water; it is but slightly soluble in water, readily in alcohol, ether, and chloroform. The general characters also resemble those of atropine and hyosciamine, so much so that no difference between them is to be recognized by ordinary reactions. Physiological experiments by Professor Kobert, proved the action of this alkaloid and hyoscine to be the same; from atropine, however, some important differences were pointed out. Upon the pulse, atropine produces an acceleration in the rate, while scopolamine, even in maximum doses, fails to produce this effect Atropine in larger doses acts upon the brain by producing delirium and, at times, attacks of mania; the other alkaloid does not produce any excitement, but operates generally in an opposite manner. Scopolamine rather tends to paralyze the functions of the cerebral cortex and to retard the heart's action. Its mydriatic action in common with that of all the alkaloids is very marked.

Its value in ophthalmic practice has been very carefully studied and reported. Rählmann (*The Therap. Gaz.*, May, 1893) used, upon normal and diseased eyes, for over half a year, samples sent to him by Professor Kobert. He concludes that scopolamine as a mydriatic and antiphlogistic surpasses all other tropines, including atropine. The great advantage that he found it to possess over atropine, was the absence of any disagreeable effect upon the secretions and the appetite, so common to the use of atropine. He never observed this action to follow its use. In several cases of iritis and episcleritis, when the powers of the body were depressed by the want of appetite, the new alkaloid not only produced an improvement in the condition of the eye, but also maintained the general health of the body. It also does not seem to influence the intra-ocular pressure, which would indicate it to be of great value in the treatment of glaucomatous eyes. The hydrochloride of scopolamine, the salt generally employed, he found to operate about five times as powerfully as atropine. It paralyzes the sphincter of the iris and the accommodation. The duration of the effect of one-fifth per cent. is about the same as a one per cent. atropine solution. He advises its use in one-tenth to one-fifth per cent. solutions; of the former, six or seven drops may be administered daily, or used every fifteen minutes during one and a half hour. The hydrochloride is a colorless, transparent crystalline powder, readily soluble in water and alcohol.

Scopoline is the name given to another product by Schmidt, which is formed from the decomposition of scopolamine by the action of baryta water. The following equation represents the chemical change that is produced:

$$\underset{\text{(Scopolamine)}}{C_{17}H_{21}NO_2} = \underset{\text{(Scopoline)}}{C_8H_{15}NO} + \underset{\text{(Atropic acid)}}{C_9H_8O_2}$$

This alteration is analogous to that of atropine or hyoscyamine under similar circumstances.

$$\underset{\text{(Atropine)}}{C_{17}H_{23}NO_3} = \underset{\text{(Tropine)}}{C_8H_{15}NO} + \underset{\text{(Atropic acid)}}{C_9H_8O_2}$$

The physiological action and therapeutic properties of scopoline have yet to be investigated.

Beaumont Small.

SENECIO MARITIMA. This plant, also known as *Cinereria maritima*, has acquired some notoriety on account of its supposed value as a remedy in ophthalmology. The plant has a reputation in Venezuela as possessing the property of removing the blindness of cataract, and two cases are reported[1] by Thomas Christy, in which improvement followed the use of the juice; two or three drops were placed in the eye three times a day. The treatment requires to be continued for several months. Further reports[2] have been made of its successful use in Calcutta, by a Dr. R. P. Banerjee. No details of the cases treated are furnished.

The genus *Senecio*, of the order *Compositæ*, is one of the most extensive genera in regard to the number of species, some nine hundred being known to botanists. They are scattered all over the globe, but are especially found in mountainous districts of South America and South Africa. *Senecio maritima* is also found in Southern Europe, on the shores of the Mediterranean Sea. It is a hardy perennial, its foliage being covered with a short white down which gives the plant a silvery appearance. It is cultivated and grown extensively in gardens as a foliage plant, for the sake of contrast with scarlet and other colors. The plant is rich in a gummy secretion, and the fresh leaves are quite glossy and glutinous.

SERUM. The blood-serum of various animals has been experimented with, during the past few years, as a means of treating tubercular disease and removing the cachexias of syphilis, malaria, and anæmia. Its use for this purpose is based upon the immunity of certain animals to certain specific poisons. It is well known that rats cannot be inoculated with the virus of anthrax, and goats and dogs are almost proof against the bacillus of tubercular disease. It has been shown by experiment, that if a few drops of the blood-serum of the rat be injected into a mouse, it is also protected against anthrax; likewise, when the serum of a goat or dog is introduced into the blood of a rabbit it, only with great difficulty, can be infected with tuberculosis. The following are the conclusions of MM. Richet and Héricourt, in announcing their discoveries to the French Academy of Sciences: 1. A rabbit having been inoculated with a culture of the tubercle bacillus, the evolution of tuberculosis can be arrested by injecting dog's blood afterward when the bacillus culture is not too virulent, but this evolution is only delayed when the culture is very virulent. 2. The effective substances of the blood, which have not yet been identified, reside in the serum, and a small dose of the latter is sufficient ($\frac{1}{2}$ c.c. per kilogramme of the rabbit). 3. The serum of dog's blood has a prophylactic action—that is to say, when injected into a healthy rabbit it prevents the development of experimental tuberculosis at a later period. 4. The serum of a dog which has been previously inoculated with tuberculosis seems to be more efficacious in a healthy rabbit, but, on the contrary, seems to aggravate the disease when injected into a rabbit already tuberculized.

These experimental researches led to the employment of serum in human subjects. MM. Bernheim and Lépine used the serum of the goat, but this has been replaced by that procured from the dog, which is now most generally used. Dr. Beretta, describing the results of this method of treatment (*British Medical Journal*, November 14, 1891), states that in two-thirds of the cases in which it had been used a real improvement, more or less marked, was observed. "The patient quickly recovered his strength, appetite, and power of movement, while his weight gradually increased. As a rule, after a few injections the patient sleeps better, the digestive functions become more regular; in some cases the

coughing, expectoration, sweating, and hæmoptysis are diminished." The patients were in the first stage, or early in the second stage. In more advanced cases a marked improvement was noticed at first, but did not continue. He sums up: "Dog's serum, in men as in animals, does not seem to have a special curative action against tuberculosis, but it possesses a powerful action, if not against the microbe, at least against its effects. It seems to act as a powerful tonic, and indirectly, by improving the general nutrition, puts the patient in a better condition to overcome his terrible disease."

The preparation of the serum, or *hæmocyne*, as it is termed, is made with great care. The blood is taken from the carotid artery of a healthy dog and received in a vessel, under strict antiseptic precautions. The serum separates, and on the following day is drawn into glass pipettes and the ends closed, all the vessels and appliances being sterilized. A careful examination of the blood and organs of the dog is made before the serum is used. The serum is injected subcutaneously in the cellular tissue of the trunk or limbs, one or more cubic centimetres being used every two days. No ill effects have been traced to this method of employing the remedy.

This method of treating tuberculosis in man has not proved the success its authors seemed to expect, but it has opened a wide field of experimental work with a promising future. The object now is to render an animal immune by inoculation and utilize the serum, not only as a protective against the disease, but also to counteract the poison when present in the system, and produce a cure. The result of this work upon animals has proved encouraging, but time alone can tell of what practical benefit it may prove to man.

Beaumont Small.

SHADOW-TEST.* "Keratoscopy," "Retinoscopy," "Retino-skiascopy," "Korescopy," and other names. An objective method of determining the refraction of the eye.

When, from a certain distance, an observer throws light into an eye by means of a perforated mirror, on looking through the hole in the mirror he sees the entire pupil illuminated with a reddish light. If, now, the mirror is slightly rotated, a dark segment ("shadow") comes into view and, increasing as the mirror is rotated, presently extends over and darkens the entire pupil. The direction in which the "shadow" grows, *i.e.*, the direction in which the border of the shadow moves, whether in the same or in the opposite direction to that in which the mirror is rotated, depends, with certain limitations, on the refraction (hypermetropia, emmetropia, or myopia) of the observed eye, and affords a means, when the necessary conditions are fulfilled, of measuring its refraction.

The perforated mirror used in the shadow-test may be either plane or concave.

1. We will assume that a plane mirror is used, and that the observer's eye, which is immediately behind the perforation, is stationed at a distance of one metre from the observed eye. The mirror is now adjusted to reflect light, preferably from an Argand burner, directly upon the observed eye, whose pupil is seen filled with a uniform red light. On rotating the mirror to the right (*i.e.*, turning the left side of the mirror forward) a dark "shadow" appears at the left side (*i.e.*, to the observer's left) of the pupil and passes over it, increasing from left to right, until the entire pupil is darkened. Similarly, on rotating the mirror to the left, the shadow appears at the right side of the pupil and passes over it from right to left.

This movement of the border of the shadow in the direction of the rotation of the mirror, occurs whenever the focus of the observed eye for pencils originating at its fundus (*i.e.*, the far-point of the observed eye) falls elsewhere than between the observer's and the observed eye. When, as we have assumed, the observer's eye is stationed at a distance of one metre, the observed eye may be either hypermetropic, emmetropic, or myopic in any degree less than 1 D.

2. Rotating the (plane) mirror to the right, the "shadow" appears at the right side of the pupil and passes over it from right to left; or, rotating the mirror to the left, the shadow appears at the left side of the pupil and passes over it from left to right.

This movement of the border of the shadow in a direction opposite to that of the rotation of the mirror, occurs when the focus of the observed eye for pencils originating at its fundus (*i.e.*, the far-point of the observed eye) falls within the distance at which the observer's eye is stationed. In our assumed case this distance is taken equal to one metre; the observed eye is therefore myopic in some degree greater than 1 D.

3. Rotating the (plane) mirror in any direction, no "shadow" is seen, but the illumination of the pupil fades gradually into darkness. This fading out of the illumination of the pupil in its totality, without any appearance of a moving shadow, occurs only in the case in which the focus of the observed eye for pencils originating at its fundus (*i.e.*, the far-point of the observed eye) falls at the exact distance at which the observer's eye is stationed, which in our assumed case has been taken equal to one metre; the observed eye is therefore myopic, and its myopia is equal to 1 D.

4. Substituting for the plane mirror a concave mirror of short focus, in which case a real image of the flame is formed between the observer's and the observed eye, the "shadow" is seen to move in a direction opposite to that in which it moves when the plane mirror is used.

These facts have been utilized for the practical determination of the refraction in several different ways, two of which have been especially cultivated.

I. The observer, stationed at a distance of one metre, and using a concave mirror preferably of about twenty centimetres focus, throws light from an Argand burner placed beside or above the patient's head, into the eye whose refraction is to be investigated. If on rotating the (concave) mirror in any direction, he sees the "shadow" moving in the opposite direction, he concludes that the eye is either hypermetropic, emmetropic, or myopic in some degree less than 1 D. Convex glasses, of progressively increasing strength, are then placed, one after another, in a trial-frame before the observed eye, until a glass is found through which no shadow-movement is discernible in the transition from the illuminated to the darkened state of the pupil. The combination of the observed eye and this convex glass represents myopia of 1 D., and the subtraction of 1 D. from the value of the glass gives the refraction of the eye. For example, if the convex glass measures 3.5 D., the refraction is H=2.5 D.; if the convex glass measures just 1 D., the eye is emmetropic; if without a glass no moving shadow is seen, the refraction is M=1 D.

If, on rotating the (concave) mirror, the shadow is seen moving in the same direction, the presence of myopia of a higher grade than 1 D. is established; concave glasses, of progressively increasing strength, are then placed, one after another, in front of the observed eye, until a glass is found through which no shadow-movement is seen. The combination of the observed eye and this concave glass represents myopia of 1 D., and the addition of 1 D. to the value of the glass gives the actual myopia.

This is the method advocated by Cuignet, Parent, and others.

II. The observer uses a plain mirror, and does not keep at a fixed distance from the observed eye. We will suppose that he first stations himself at a distance of one-half metre, and sees the "shadow" moving in the same direction as that in which the mirror is rotated, thus establishing the fact that the eye is either hypermetropic, emmetropic, or myopic in some degree less than 2 D. A convex glass of sufficient strength to render the observed eye myopic in excess of 2 D. is then placed before it in a trial-frame, thus causing an image of its fundus to be formed in front of the eye of the observer. The observer next approaches the observed eye until he reaches

* See foot-note at bottom of page 701.

a point at which no moving shadow is discernible—*point of reversal.* The observer's eye is now at the far-point of the observed eye as modified by the convex glass, and the distance from eye to eye is measured by means of a rule or a tape-measure. The reciprocal of the fractional part of a metre thus measured represents, in dioptries, the refraction of the observed eye plus the convex glass, and the subtraction of the value of this glass gives the refraction of the eye.

When the observed eye is myopic in excess of 2 D., so that its far-point lies within the distance of one-half metre at which the eye of the observer is stationed, the movement of the shadow is in the direction opposite to that in which the mirror is rotated, and the distance of the point of reversal from the observed eye gives the measure of the myopia.

When the myopia of the observed eye is in excess of 4 D. or 5 D., the point of reversal falls too near the eye for an entirely trustworthy measurement of its distance. In such a case a concave glass, of sufficient strength to carry the far-point back to a distance of from one-quarter metre to one-half metre, is placed before the observed eye, and the value of this (concave) glass must be added to that obtained by measuring the distance of the point of reversal.

This is the method advocated by Chibret, Schweigger, and others.

In emmetropia, and in simple ametropia (hypermetropia and myopia), the movement of the mirrored image of the flame, whether virtual or real, and that of the "shadow" are always in one and the same plane passing through the observer's and the observed eye. The same is true also in astigmatism whenever the plane in which the image moves, as determined by the direction in which the mirror is rotated, passes through either of the two principal meridians of the observed eye. The shadow-test is, therefore, perfectly adapted to the measurement of the refraction of an astigmatic eye in each of its two principal meridians. If, however, the shadow is seen to move in a plane other than that determined by the direction of the rotation of the mirror (see Fig. 574), it is certain both

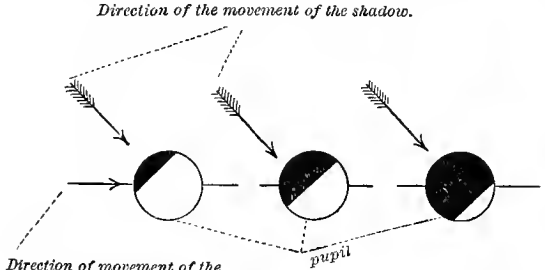

FIG. 574.

that the observed eye is astigmatic, and that the plane in which the mirrored image moves does not pass through either of its principal meridians. To find a principal meridian, whether of greatest or least refraction, it is then only necessary to vary the direction in which the mirror is rotated, until the shadow is seen to move in the same or in the opposite direction. The statement made by different writers, that the direction of the obliquely moving shadow corresponds to that of one or the other of the two principal meridians, is erroneous.

The idea of utilizing the direction of the movement of the "shadow" in the pupil for the practical determination of the refraction originated with Cuignet (1873), but he gave a wrong explanation of the phenomenon and so was led to give to the procedure the very unsuitable name, "keratoscopy." Landolt (1878) was the first to propose a nearly correct theory, and his and Parent's descriptions have contributed largely to the popularization of the method. Credit must also be given to Chibret (1882) for the important modification of the procedure in which the plane mirror is used at a varying distance. Leroy and Monoyer have further developed the theory, which, strange to say, had been erroneously, or at best inadequately, stated during a good number of years.

The theory of the shadow-test will be best understood if we consider a few special cases :

I. We will assume that the observed eye is emmetropic, and that the test is made with a plane mirror at a distance of one-half metre. An image of the source of light (Argand burner) is formed at the fundus of the observed eye, which, within the limits of this image, is strongly illuminated so that every point gives out rays of light as if it were self-luminous. The details of this illuminated area at the fundus are, however, indistinguishable, or at best imperfectly distinguishable, inasmuch as, by the conditions of the test, the observer's eye is accommodated, not for the fundus, but for the pupil of the observed eye. The illuminated area is seen, therefore, in circles of confusion, consequently as a more or less diffuse red light shining through the pupil.

How much of the illuminated area is, in any case, visible to the observer, is determined in part by the diameter of the pupil of the observed eye, and in part also by the size of the hole in the mirror, or, if this is rather large, by the diameter of the pupil of the observer's eye. Let $a\,a'$ (Fig. 575, *I*) represent a portion of the illuminated area (image of the flame) at the fundus of the observed eye, which we assume to be directed upon the hole in the mirror, consequently upon the pupil of the eye of the observer. Let $a\,P\,p\,\pi$ represent a limiting ray passing out of the pupil of the observed eye to enter the pupil of the observer's eye ; similarly, let a' represent the origin of another limiting ray, as determined by the points P′ and p', meeting the retina of the observer's eye at π'. Now P P′ and $p'\,p$ represent, respectively, the diameters of the two (circular) pupils, consequently $a\,a'$ and $\pi\,\pi'$ must also represent diameters of circles. We will call the circular area $a\,a'$ the *visible circle.* Inasmuch as the illuminated area (image of an Argand burner when the distance of the mirror is taken anywhere between the limits of one metre and one-quarter metre) is considerably larger than the visible circle, the entire pupil P P′ will be lighted up, and the visible circle $a\,a'$ will coincide throughout with the two pupils, P P′ and $p\,p'$, and with the circle $\pi\,\pi'$ at the fundus of the eye of the observer. But we have already seen that the visible circle $a\,a'$ is pictured at $\pi\,\pi'$ in circles of confusion ; hence the impression made on the observer is rather that of the illuminated pupil P P′ than of the circle $a\,a'$.

To explain the phenomenon of the moving "shadow" we will suppose that the observer, whose attention is fixed on the illuminating pupil PP′ of the observed eye, now rotates the mirror a little to the right (see Fig. 576), thus displacing the mirrored (virtual) image of the flame to the left, consequently displacing the real image of the flame at the fundus of the observed eye to the right. The displaced image of the flame, as it passes over the visible circle, presently leaves a segment of the latter without illumination, consequently a segment of the pupil P P′ darkened (see Fig. 577). As already explained, the border of this dark segment is seen somewhat imperfectly defined, thus suggesting a shadow with its penumbra, and accounting, in a way, for the name "shadow-test."

It will be observed that in this case (emmetropia of the observed eye) the growth of the darkened segment of the pupil (movement of the shadow) is in the same direction as that in which the (plane) mirror is rotated, the reversed movement at π, or at π', being perceived as a direct movement at a or at a', consequently at P or at P′.

II. We will now assume that the observed eye is hypermetropic, the other conditions remaining as before (see Fig. 575, *II*). Comparing *I* and *II*, Fig. 575, it is evident that nothing essential has been changed, as regards either the formation of the "shadow" or the direction of its movement. The illuminated area (image of the flame) is, however, smaller, and the visible circle larger, than in the case of emmetropia of the observed eye. The dark border of the illuminated area will therefore pass the limit of the visible circle more quickly (the rate of rota-

tion of the mirror being assumed to be unchanged), but more time will be required for its transit. We have seen that the apparent diameter of the visible circle is the same as that of the pupil; the rate of passage of the shadow across the pupil is therefore slower in hypermetropia than in emmetropia.

In hypermetropia of the observed eye the conditions for obtaining a clearer view of the details of the fundus, when the eye of the observer is accommodated for its

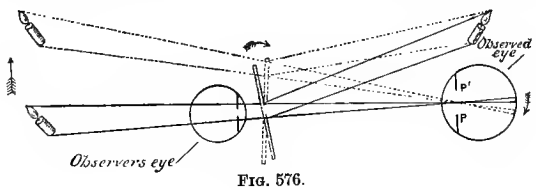

Fig. 576.

pupil, are more favorable than in emmetropia, and the higher the grade of the hypermetropia (*i.e.*, the less the distance at which the virtual image, $h\,h'$, of the visible circle lies behind the plane of the pupil) the more clearly will the retinal vessels, etc., be seen. On the other hand, hypermetropia of the observed eye is unfavorable for the accurate focussing of the image of the flame on its retina, and for this reason the outlines of this image are less sharply defined than in emmetropia. The advantage, to the observer, of the clearer view which he obtains of the image of the flame is, however, greater than the disadvantage resulting from its less perfect definition; hence the free border of the shadow, as it traverses the pupil, appears more sharply defined in hypermetropia than in emmetropia, and the higher the grade of the hypermetropia, the more distinct, on the whole, does the shadow appear.

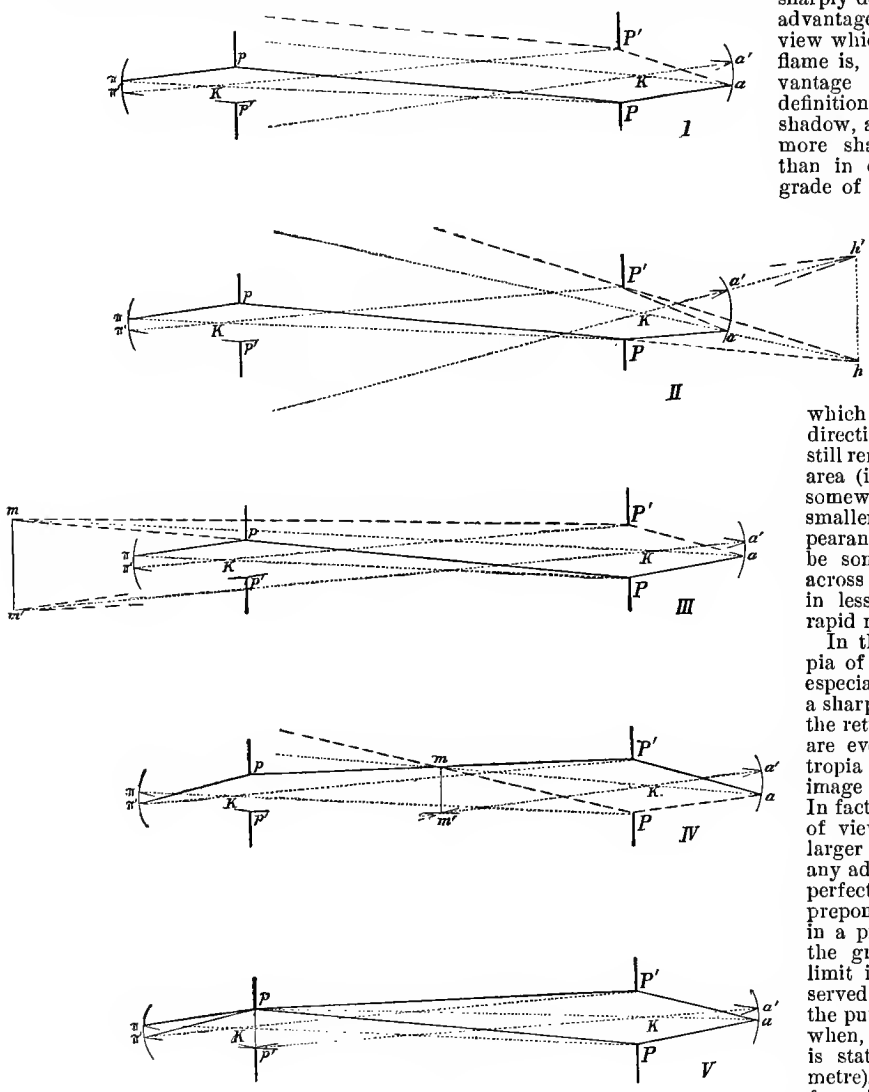

Fig. 575.

III. The observed eye is assumed to be myopic in some degree less than 2 D., the observer being stationed, as before, at a distance of one-half metre (see Fig. 575, *III*). Comparing *III* with *I* and *II*, Fig. 575, we see by inspection that the conditions which determine the formation and the direction of movement of the "shadow" still remain unchanged. The illuminated area (image of the flame) is, however, somewhat larger, and the visible circle smaller than in emmetropia. The appearance of the shadow will therefore be somewhat retarded, but its transit across the pupil will be accomplished in less time, consequently at a more rapid rate of movement.

In the case under consideration (myopia of less than 2 D.) the conditions are especially favorable for the formation of a sharply defined image of the flame on the retina of the observed eye, but they are even less favorable than in emmetropia for the accurate picturing of this image on the retina of the observer's eye. In fact, the disadvantage to the observer of viewing the image of the flame in larger circles of confusion outweighs any advantage accruing from the more perfect definition of this image, and this preponderance of disadvantage increases, in a progressively augmenting ratio, as the grade of myopia approaches the limit in which the far-point of the observed eye lies exactly at the distance of the pupil of the observer's eye (*i.e.*, 2 D., when, as we have assumed, the observer is stationed at a distance of one-half metre). In this limiting position of the far-point of the observed eye (point of reversal) no shadow-outline, consequently no shadow-movement, is discernible.

IV. The far-point of the observed eye is assumed to lie in front of the eye of the observer (myopia of the observed eye in excess of 2 D., when the observer is stationed at the assumed distance of one-half metre—see Fig. 575, *IV*). A new condition now comes into play.

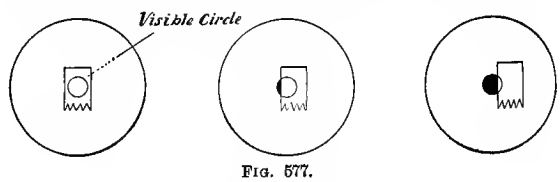

Fig. 577.

A real image, $m'm$, of the visible circle $a\,a'$ is formed at the far-point of the observed eye. Of this image a second image $\pi\pi'$ (which is a twice-inverted, therefore an erect image of $a\,a'$) is pictured on the retina of the eye of

the observer, who sees the image of the flame at $a\ a'$ inverted, and the direction of its motion, consequently the direction of the shadow-movement, reversed. The higher the grade of the myopia, the larger is the illuminated area (image of the flame), and the larger, also, is the visible circle, the latter increasing, however, at a greater rate than the former. Conversely, the lower the grade of the myopia within the assumed limit of 2 D. (*i.e.*, the nearer to the plane $p'\ p$ of the pupil of the observer's eye the real image $m'm$ falls), the smaller is the portion of the fundus at $a\ a'$—*i.e.*, the visible circle—from which rays of light can enter the eye of the observer. Again, the higher the grade of the myopia (*i.e.*, the nearer to the plane P P' of the pupil of the observed eye the real image $m'm$ falls), the sharper will be the definition of the shadow-outline. Conversely, the lower the grade of the myopia (*i.e.*, the nearer to $p'\ p$ the real image $m'\ m$ falls), the less advantageous will be the conditions for seeing it distinctly; consequently the more imperfect will be the definition of the shadow-outline, until, in the assumed limit of 2 D., no shadow-outline, consequently no shadow-movement, will be seen.

V. The far-point of the observed eye is assumed to lie at the exact distance of the pupil of the observer's eye (myopia of 2 D., when the observer is stationed at the assumed distance of one-half metre—see Fig. 575, *V*). In this case the real image of the visible circle (*cf. V.*, with *III* and *IV*, Fig. 575) is formed at and fills the pupil $p\ p'$ of the eye of the observer, the point p corresponding to a, and p' to a'. Now the outermost rays, a P p and a P' p, of the limiting pencil originating at a to pass out of the pupil of the observed eye and enter the pupil of the observer's eye, are refracted to π and π', respectively, at the retina of the observer; and, in like manner, all intermediate rays belonging to the same pencil are refracted each to its own point intermediate between π and π'; hence every point in the circle $\pi\pi'$ is faintly illuminated by rays emanating from a. Similarly, the limiting pencil originating at a', likewise all pencils originating at points lying between a and a', contribute each its own share to the general illumination of the circle $\pi\pi'$, consequently to the illumination of P P', the pupil of the observed eye, in its totality. The effect of the rotation of the mirror is manifested, therefore, by a gradual fading out of the light in the pupil, and not, as in cases I. to IV. by the appearance of a moving "shadow." It will be further observed (*cf. I, II, III, IV*, and *V*, Fig. 575) that in this case the diameter of the visible circle (*i.e.*, of the area at the fundus of the observed eye from which rays of light can pass out through its pupil to enter the pupil of the observer's eye) is at its minimum.

Comparing these several cases, we draw the following deductions:

a. Appearance and direction of movement of the shadow. Whenever a "shadow," appearing at the side of the pupil of the observed eye, is seen to move in the same direction as that in which the (plane) mirror is rotated, the eye is either hypermetropic, emmetropic, or myopic in such (lower) degree that its far-point lies behind the eye of the observer—cases I to III.

When the "shadow" is seen to move in the direction opposite to that in which the (plane) mirror is rotated, the eye is myopic in such (higher) degree that its far-point lies in front of the eye of the observer—case IV.
